SMALL ANIMAL AND EXOTICS EDITION

BOOK 1

Published by the NAVC, 5003 SW 41st Blvd., Gainesville, FL 32608. Copyright 2008 by the NAVC. All rights reserved. No part of this publication may be reproduced, stored in a retrieval system, or transmitted without written permission from the NAVC.

The ideas, content and conclusions presented in these Proceedings are strictly those of the contributors and do not necessarily represent the viewpoint, position, or endorsement of the NAVC. The NAVC and the contributors do not take responsibility for information provided on dosages and methods of applications of drugs mentioned in these Proceedings. This information must be verified by the user from appropriate literature and/or additional sources.

While all contributors were invited to submit manuscripts for the general sessions, some chose not to do so. The NAVC regrets these omissions, but has done everything possible to ensure a comprehensive Proceedings for the NAVC Conference 2008.

"Special thanks for the assistance received from Robin Hipple, Medical Editor and Marcy Bryant, Layout."

About the Cover: **Jim Wilson's** fascination with animals has influenced many aspects of his life including his career choice. A professional wildlife artist for over thirty five years, Jim spends many hours seeking out and researching his subjects for his detailed pen and ink drawings. He relies on reference material gathered from field work, museums, zoos, veterinary hospitals and rehabilitation facilities. His camera is a constant companion, providing a permanent collection of reference photos. Jim's work has been featured in a variety of NAVC material since 1992.

TABLE OF CONTENTS
Small Animal Book 1: Pages 1–962

ALTERNATIVE MEDICINE

Introduction to Veterinary Acupuncture
Mary S. Battistella 1

The Smelly, Itchy Dog: A Case Report
Mary S. Battisella 3

Veterinary Apitherapy – Or the Therapy that Stings
Sagiv Ben-Yakir 5

Neuropathy Treated by Bee Venom Therapy
Sagiv Ben-Yakir 7

Feline Thromboembolism (Saddle Thrombus) Treated by Medical Leeches
Sagiv Ben-Yakir 8

Evidence-Based Acupuncture
Sagiv Ben-Yakir 9

A Novel Approach to Veterinary Dermatology
Sagiv Ben-Yakir 11

Hemoacupuncture, or the Therapy that Sticks
Sagiv Ben-Yakir 13

Prolotherapy – A Great CAVM Method to Solve Musculoskeltal Problems
Sagiv Ben-Yakir 16

Homotoxicology – An Introduction of the Modern Veterinary Homeopathy into the Daily Activities of a Busy Veterinary Clinic
Sagiv Ben-Yakir 19

TCM Approach to Cancer – Part 1
Constance A. DiNatale 23

TCM Approach to Cancer – Part 2
Constance A. DiNatale 25

A Renaissance – The Tradition and Science Behind the Use of Herbs in Veterinary Medicine
Barbara Fougere 27

Veterinary Herbal Medicine: The Science Behind the Tradition – Is There a Scientific Rationale for Herb Use and Where Do I Find It?
Barbara Fougere 32

Herbal Manufacture – How Herbal Medicines Are Made & How Do I Know if the Herbs Are Safe to Prescribe?
Barbara Fougere 37

Acute Prescribing with Herbs for Common Veterinary Conditions – Eight Herbs that Can Help Your Patients
Barbara Fougere 40

Herb-Drug Interactions – What Your Clients Are Using and What You Need to Know
Barbara Fougere 44

Herbal Medicine in Practice – Disease Management with Antioxidant Herbs
Barbara Fougere 47

Improve Treatment Outcomes with Veterinary Acupuncture
Deborah M. Mitchell 51

New Questions, Old Answers: Traditional Chinese Veterinary Medical Diagnostics
Deborah M. Mitchell 56

Save that Dying Patient! The TCM Crashbox
Deborah M. Mitchell 60

TCM Perspectives on Urinary Tract Diseases: Physiology, Diagnosis, and Treatment
Deborah M. Mitchell 63

TCM Approach to Dermatologic Disorders
Deborah M. Mitchell 70

TCM Management of Atopic Dermatitis
Deborah M. Mitchell 76

Ozone Therapy: Beyond Oxygen. The Most Needed Adjunct to Veterinary Medicine
Margo Roman 78

Food Intolerance in Our Veterinary Patients
John B. Symes 81

Viruses and Lectins – The Missing Links
John B. Symes 85

Idiopathic Epilepsy – The Dietary Solution
John B. Symes 88

Prolotherapy – A Simple, Natural Technique that Stimulates the Body to Repair Damaged/Loose Ligaments
Carvel G. Tiekert..91

ANESTHESIOLOGY

Anesthetic Complications
Christine Egger 93

Local and Regional Anesthetic and Analgesic Techniques
Christine Egger..99

Challenging Feline Anesthesia Cases
Christine Egger 104

Transdermal Fentanyl Patches and Alternatives for Long-term Analgesia
Christine Egger 108

The Preoperative Physical Examination and Interpretation of Preoperative Blood Work
Karen Faunt 110

Management of the Anesthetic Emergency
Karen Faunt 112

Evidenced-based Best Practices Pet Anesthesia for Healthy, Fractious, and Ill Patients
Will Novak 114

Looking Forward – Lessons and Conclusions
Will Novak 117

What Are those Monitors Telling You?
Lysa Pam Posner 119

Anesthesia Protocols for Challenging Canine Cases
Lysa Pam Posner 123

Morphine-Lidocaine-Ketamine (MLK)
Lysa Pam Posner 126

Butorphanol or Buprenorphine: Which Should I Use?
Lysa Pam Posner 128

Epidural Anesthesia and Analgesia: Clinical Application for Routine Surgical Use
Michael Tillson 130

Introduction to Small Animal Anesthesia Best Practices Based on Outcome Analysis
Lee Tyner 132

Perfusion Basics and Proper Use of Premedication, Tranquilization, and Immobilization
Lee Tyner 134

Safe and Effective Anesthesia Induction and Maintenance
Lee Tyner 137

BEHAVIOR

Pheromones: Recent Advances and Clinical Cases
Sharon Crowell-Davis and Mami Irimajiri 141

Practical Approach to the Treatment of Separation Anxiety in Dogs
Debra F. Horwitz 142

Separation Anxiety in Dogs, Part 1: Diagnosis and Clinical Presentation- An Evidence-Based Approach
Gary Landsberg 146

Separation Anxiety in Dogs, Part 2: Therapeutic Options- An Evidence-Based Approach
Gary Landsberg 149

Behavior Modification Case Management in Genreal Practice
Patrick Melese 152

Speaking Dog – Understanding How Dogs Signal
Karen L. Overall 155

Understanding Cats Who Fight and Why this Affects Litterbox Use
Karen L. Overall 158

Combining Medications for Maximal Effects
Karen L. Overall 162

How to Pet Dogs, How to Teach Dogs to Relax, and Why this Matters
Karen L. Overall 168

Dealing with Aggression in the Veterinary Clinic
Kersti Seksel 171

Kitten Kindy® and Puppy Preschool® – Good Practice Builders
Kersti Seksel 174

Understanding Learning Theory – Why It's Important
Kersti Seksel 177

Head Collars – Different Types, How They Work and How to Fit Them
Kersti Seksel 180

Muzzle Training
Kersti Seksel 182

CARDIOLOGY

Diagnosis and Treatment of Pericardial Effusion
Matthew W. Beal 183

Hypertension – Target Organ Damage and Therapy
Anthony P. Carr 186

Blood Pressure Measurement: Comparison of Techniques
Beate Egner 188

Sildenafil – What You Need to Know
Amara Estrada 192

Pimobendan and Heart Disease – Breaking Update
Amara Estrada 194

Low-Molecular-Weight Heparins – How to Use Them
Amara Estrada 196

Treating Feline Heart Failure
Philip R. Fox 198

Acute & Chronic Canine Heart Failure: The Role of Pimobendan
Sonya G. Gordon 201

Heart Failure and Chronic Kidney Disease: When Worlds Collide
Gregory F. Grauer, Clarke E. Atkins, and Bruce Keene 205

Patent Ductus Arteriosus: New Treatment Options
Henry W. Green, III 208

Feline Cardiomyopathies: What Do We Do for Therapy of Thromboembolic Complication
Henry W. Green, III 211

Feline Systemic Hypertension: Diagnosis and Treatment
Henry W. Green, III 213

New Test for Feline Cardiomyopathies
Henry W. Green, III 216

Clinical Cardiology Update: Congestive Heart Failure
Henry W. Green, III 218

Diagnosis and Treatment of Syncope
Henry W. Green, III 221

Diseases of the Pericardium
Henry W. Green, III 224

Diagnosis and Management of Syncope
N. Sydney Moïse 227

Feline Thromboembolism
N. Sydney Moïse 229

How to Treat Arrhythmias in the Face of Heart Failure
N. Sydney Moïse 233

Heart Failure Management
N. Sydney Moïse 237

Fainting: Bad Heart or Bad Brain?
Rebecca L. Stepien 239

CRITICAL CARE

A Practical Approach to Acid-Base Abnormalities
Matthew W. Beal 243

Approach to the Head Trauma Patient
Matthew W. Beal 247

Transfusion Medicine for the General Practitioner
Matthew W. Beal 252

Placement of Central Venous Catheters: Seldinger Technique
Matthew W. Beal 255

Every Clinic Is an Emergency Clinic: Rapid Assessment – "The First 15 Minutes"
Tim Hackett 260

Fluid Therapy
Tim Hackett 263

Use of Lactate Monitoring
Tim Hackett 266

ABCs of Acid-Base
Justine A. Lee 268

Misconceptions about Emergency and Critical Care
Justine A. Lee 272

Current Concepts in CPR
Steven L. Marks 277

Emergency Management of the Patient with Heatstroke
Michael Schaer 280

Gasping Cat – Approach to the Dyspneic Feline
Michael Schaer 283

Fluid Therapy for Critically Ill Dogs and Cats
Michael Schaer 287

Practical Pearls from the Emergency Room
Michael Schaer 291

Caring for the Critically Ill Icteric Cat
Michael Schaer 295

CYTOLOGY & DIAGNOSTICS

Bile Peritonitis – White Bile
Rick L. Cowell 299

The Complete Urinalysis
Rick L. Cowell and Dennis B. DeNicola 300

Cytology of Inflammation
John W. Harvey and Alan H. Rebar 303

Cytology of Blood
John W. Harvey and Alan H. Rebar 306

Cytology of Internal Organs
John W. Harvey and Alan H. Rebar............................308

Chemistry: Profiling and Trending
Alan H. Rebar 311

General Approach to Cytologic Interpretation
Alan H. Rebar and John W. Harvey 313

Cytology of Neoplasia
Alan H. Rebar and John W. Harvey............................315

Cytology of Bone Marrow
Alan H. Rebar and John W. Harvey 317

Urinalysis for the Clinical Detective
Meryl P. Littman 319

Chemistry Ratios for the Clinical Detective

INTRODUCTION TO VETERINARY ACUPUNCTURE

Mary S. Battistella, DVM, CVA
Kowaliga Whole Health Pet Resort
Eclectic, AL
Riverview Animal Clinic
Birmingham, AL

Veterinary acupuncture is believed to have been in use almost since the first records of acupuncture. The first written record of veterinary acupuncture is a treatise on the use of acupuncture on Indian elephants, estimated to have been written 3000 years ago. One of the oldest documents on Traditional Chinese Medicine (TCM) was published sometime between 400 and 200 BC, the *Huang Ti Nei Ching*, or *The Yellow Emperor's Classic of Internal Medicine*. It is considered the basis of TCM and describes the Oriental philosophy of anatomy, physiology, pathology, diagnosis, and treatment of maladies of that time. Included in TCM are acupuncture, moxibustion, Tui-Na (manipulative therapy or massage), Qi-Gung (breathing exercises), Shu-Shieh (nutrition and diet), and herbal medicine.[1]

Shun Yang (also called Pao Lo), 480 BC, was considered the first full-time practitioner of Chinese veterinary medicine on record. He is considered the father of the profession in China. Acupuncture was introduced in the West by a French Jesuit, P.P. Harvieu, who published the first European work on acupuncture in 1671. Acupuncture appears to have been introduced in the United States in the nineteenth century. In 1893, Sir William Osler mentioned acupuncture as a treatment for lumbago in the textbook *The Principles and Practice of Medicine.*

The International Veterinary Acupuncture Society (IVAS) was formed in 1974 to promote "excellence in the practice of veterinary acupuncture as an integral part of the total veterinary health delivery system." IVAS offers a certification exam and training courses throughout the world. Annual congresses are held where there is an international board of delegates that meets, as well as presentation of research papers and acupuncture techniques.

Veterinary acupuncture has become known as the use of needles in stimulating acupuncture points for the purpose of relieving pain or improving the function of various systems of an animal's body. In actuality, stimulation by needles is only one form of acupuncture; it also includes stimulating acupuncture points with finger pressure, heat, ultrasound, laser, aquapuncture, electroacupuncture, and implantation.

Histologically, acupuncture points are cutaneous areas supplied by relatively high concentrations of free nerve endings, nerve bundles and nerve plexi, mast cells, lymphatics, capillaries, and venules.[2] No unique structures are found at acupuncture points, but most are associated with neural structures: muscle motor points, foci of nerves overlapping in the sagittal plane, loci of nerve plexi or superficial cutaneous nerves. Approximately 70% of acupuncture points correspond to trigger points.[3] Acupuncture points can be objectively measured as areas of lower electrical resistance compared with the surrounding skin. Normal dry skin has a direct current (DC) resistance of 200,000 to 2,000,000 ohms, which decreases to approximately 50,000 ohms at acupuncture points.[4] Because of this electrical phenomenon, acupuncture point finders have been developed that measure resistance based on Ohm's law. Point finders are often used by students of acupuncture, until they have developed the feel for palpating acupuncture points.

Numerous studies have been done on acute pain in animals and humans. Acupuncture analgesia from needling true points is superior to sham points. Point specificity has not been well studied in the treatment of chronic pain, but in Pomeranz' study in patients with chronic pain, placebo effect was quite strong, working in 30% to 35% of patients, compared with 33% to 50% of those with sham needling and 55% to 80% with needling true points.

One of the theories that has been used to explain acupunctures effectiveness in analgesia is called the gate theory. It proposes that impulses in fast conducting, large diameter afferent nerve fibers conveying information about pressure, touch, and vibration to the dorsal horn, synapse on inhibitory interneurons that close the "gate" to the ascending pain transmission before the impulses arrive from the slowly conducting nociceptive fibers. This would prevent pain impulses from reaching the brain for perception. This theory does not address the continuation of analgesia beyond the cessation of stimulation. It is very likely that it works through an endogenous pain inhibitory system. This system involves descending impulses from the brainstem to the inhibitory complex in the dorsal horn, where it blocks pain impulses from being relayed to the brain. Endogenous substances such as enkephlins and seratonin are mediators in this system.

In order to do acupuncture, a practitioner must learn the anatomic location of acupuncture points and the physiologic consequence of stimulating each point, individually and in combination with other points. After making a diagnosis and determining that acupuncture is indicated, a practitioner must select the points to be used (prescription), establish the duration of the treatment session, and choose the type of stimulus.

In clinical practice, veterinary acupuncture is utilized for its diagnostic, therapeutic, and hypoalgesic properties. A thorough patient history is required for diagnosis according to Traditional Chinese Medicine (TCM), and is integrated into our Western thought and diagnosis. For example, an old pet may be presented that has difficulty getting up and it has been determined radiologically that the pet has extensive spondylosis in the lumbar spine and arthritis in both hips. In Western practice, this pet would probably be treated with non-steroidal anti-inflammatory drugs. As an important part of the history in developing a diagnosis for acupuncture treatment, it is also important to know other aspects of the problem, such as what is the energy level of the pet? Does the patient prefer to lie on the kitchen floor (cold surface) as opposed to the carpet? Does he prefer the warmth of the sun to the air conditioned room? How much water does he drink? Does he have a tendency to drink large quantities at a time? What is his appetite like? History of any past traumas or surgery? ...

Questions of this nature guide the practitioner in determining the energy of the pet, whether the condition involves heat or cold pain, and which treatment options might be useful. The health history can direct the practitioner to the constitution of the pet. Pain and arthritis are both considered to be due to the interruption of the flow of Qi through the affected area. Qi (pronounced "chi") is the name for the vital energy and nutrition that flows through our body. It is like a form of electricity that travels with the blood and through the tissues to keep the cells metabolizing at their optimum. If there was never an interruption in the flow, including the cellular level, there would never be buildup of osteophytes that cause arthritis. This is idealistic, for any type of trauma can cause an interruption of flow of Qi and cause pain. A bruise is a good example of the "stagnation of blood and Qi." Not only trauma can cause the decrease in the flow of Qi, emotional stress, deficiency of fluids, body confirmation, genetics, and deficiency of energy may also contribute to decreased flow. Acupuncture is a way to help direct the flow of Qi in the body. It cannot, however, significantly add energy that is not already within the body. It is an excellent way to tap into reserves within the body so that they can be utilized where needed. We derive energy through the food we eat, and the air that we breathe. The Chinese use herbal therapy and food therapy to aide in building energy as well as breathing exercises.

The acupuncture meridian system has been compared with an electrical system with dimmer switches along the way. Acupuncture points act as dimmer switches or relay switches that can regulate the flow of electricity or Qi. There are 12 main pairs of these complex pathways called meridians through which the Qi flows. Each of the 12 major meridians is associated with an internal organ and is like a power line running through the body. There are also two unpaired meridians that course the midline on the front of the body and the midline on the back of the body. For example, the Heart meridian starts in the area of the axilla and courses down the medial side of the arm and ends on the outside of the little finger by the fingernail. When someone is having a heart attack, sensation along this pathway is sometimes evident.

Applications in veterinary practice include:

- **Diagnostic tool**
- **Musculoskeletal system**
  - Intervertebral disk disease

  - Hip dysplasia – Basic point prescription:
    - GB29 - 1/3 the distance from the greater trochanter to the cranial dorsal iliac spine
    - GB 30 - Midway between the greater trochanter and the tuber ischii
    - BL 54 - Depression just dorsal to the greater trochanter
  - Promote bone healing
  - Muscular weakness
  - Arthritis
- **Neurological System**
  - Nerve trauma
  - Seizures
  - Wobblers
- **Miscellaneous**
  - Wound healing
  - Anestrus and other reproductive problems
  - Abdominal pain with enteritis
  - Inflammation
  - Decreased energy levels
  - Cancer patient support
  - In adjunct to current therapies in dealing with renal disease
  - Emergency Point: GV 26 - In the intersection of the "T" formed below the nose, in the filtrum

The most commonly used forms of acupuncture in animals are dry needling, aquapuncture, laser, acupressure, moxibustion, electroacupuncture, ultrasound, and implants.

THE SMELLY, ITCHY DOG: A CASE REPORT

Mary S. Battistella, DVM, CVA
Kowaliga Whole Health Pet Resort
Eclectic, AL
Riverview Animal Clinic
Birmingham, AL

A 6-year-old Scottish deerhound was presented for hair loss and itching, especially around the eyes and mouth, but also the ear pinnae. There was also hair loss on the backs of the hind legs. The owner had been giving prednisone 20 mg several times a week, but wanted to reduce the dosage because she had other deerhounds that had had problems on steroids.

On examination, there was hair loss on the face and back legs. The skin was mildly red and had an odor; the skin was thickened. The pulse was rapid and weaker than I would have expected for the breed. The tongue and gums were red, and the dog was panting. The face appeared to be more pruritic than the legs, but there was not much scratching in other areas. Appetite was good. The dog was fed a premium brand dry food and was on a fatty acid supplement.

SYMPTOMS:	**TCM**:
• Itching or pruritus	Wind
• Mildly red skin	Heat (deficiency or excess)
• Thickened skin	Damp or phlegm
• Odor	Heat or Damp Heat
• Rapid pulse	Heat
• Pulse not full	Deficiency (blood)
• Hair loss	Deficiency or phlegm
• Panting	Heat or nervousness

DIAGNOSIS

Deficiency heat with Wind and Damp

TREATMENT PRINCIPLE

- Eliminate Wind and Damp and Heat
- Nourish the Blood
- Move the Blood

TREATMENT FORMULAS

(Long Dan Xie Gan Tang)

Long Dan Xie Gan Tang, Jia Hua Ban Jie Du Tang - Itching

(9)	*10g RADIX GENTIANAE long dan cao	clear damp heat; itching
(12)	10g RADIX SCUTELLARIAE huang qin	drain and clear heat, toxic heat from skin
(12)	10g FRUCTUS GARDENIAE zhi zi	clear toxic heat and damp heat
(6)	10g CAULIS CLEMATIDIS oder AKEBIAE mu tong	drain damp heat and toxic heat
(15)	10g SEMEN PLANTAGINIS che qian zi	drain and clear damp heat
(12)	10g RHIZOMA ALISMATIS ze xie	drain damp and heat; nourish yin
(9)	RADIX BUPLEURI chai hu	disperse stagnation, ears
(15)	30g RADIX REHMANNIAE sheng di huang	tonify blood
(12)	RADIX ANGELICAE SINENSIS dang gui	treat blood def of skin
(6)	RADIX GLYCYRRHIZAE gan cao	clear heat from skin
	10g CORTEX MOUTAN RADICIS mu dan pi	soften blood stasis, replenish yin
	12g FOLIUM ISATIDIS da qing ye	drain damp
	12g PORIA COCOS fu ling	drain damp
	10g FLOS LONICERA jin yin hua	clear damp heat
	10g FRUCTUS FORSYTHIAE lian qiao	clear damp heat
	* 15g CORTEX DICTAMNI RADICIS bai xian pi	clear heat

After clearing the damp and heat from the skin, the inflammation had greatly decreased but the skin was dry and flakey. Hair regrowth was progressing. The formula was changed to one that addressed the deficiency of yin and blood, and the itching

(Huo Xue Qu Feng Tang)

Huo Xue Qu Feng Tang - Itching

(9g)	10g RADIX ANGELICAE SINENSIS) dang gui wei	replenish blood, disperse qi
(9g)	10g RADIX PAEONIAE RUBRAE chi shao	disperse blood stagnation, heat
(9g)	10g SEMEN PERSICAE tao ren	invigorate blood, soften mass
(9g)	10g FLOS CARTHAMI hong hua	remove heat, toxic heat; eyes
(9g)	* 10g HERBA SCHIZONEPETAE jing jie	remove blood deficiency wind; itch
(9g)	* 12g FRUCTUS TRIBULI bai ji li	remove blood deficiency wind; itch
(6g)	6g RADIX GLYCYRRHIZAE gan cao	clear heat from skin
	* 6g RADIX LIGUSTICI CHUANXIONG chuan xiong	remove wind from skin, disperses; itch
	* 6g PERIOSTRACUM CICADAE chan tui	remove toxic heat, wind heat, itch

Plus Envoy Herbs

6g RADIX ANGELICAE DAHURICAE bai zhi	nose, face; clear wind, damp, heat
4g CORTEX PHELLODENDRI huang bai	ears, face; clear damp, heat
6g FRUCTUS LIGUSTRI LUCIDI nu zhen zi	eyes; remove deficiency fire, nourish yin, hair loss

May Add Nourishing Herbs:

10g HERBA ECLIPTAE PROSTRATAE han lian cao	nourish blood, yin; deficiency hair loss
10g SEMEN SESAMI INDICI hei zhi ma	nourish blood; deficiency hair loss

Other popular formulas that are available are the Jing Tang Damp Heat Skin and Kan Herbs Veterinary Formula for Damp and Heat

The Jing Tang Damp Heat Skin:

SCUTELLARIA	huang qin	clear damp- heat; detoxify
PHELLODENDRON	huang bai	clear damp- heat; detoxify
SOPHORA	ku shen	clear damp- heat; detoxify; relieve itch
REHMANNIA	sheng di huang	cool blood and nourish yin
ISATIS	ban lang gen	clear heat, detoxify
PLANTAGO	che qian zi	clear damp- heat; benefit urination
TALC,	hua shi	clear damp- heat; benefit urination

Si Miao San

PHELLODENDRON	huang bai
ATRACTYLODES	cang zhu
ACHYRANTHES	huai niu xi
COICIS	yi yi ren

VETERINARY APITHERAPY – OR THE THERAPY THAT STINGS

Sagiv Ben-Yakir, BSC, DVM, MRCVS
Hod-Hasharon Veterinary Clinic
Hod-Hasharon, Israel

Veterinary apitherapy is the medical use of honeybee products for the benefit of sick animals. It can include the use of honey, pollen, propolis, royal jelly, and bee venom, but most commonly refers to the use of bee venom, also called Veterinary Bee Venom Therapy (VBVT), which is the application or injection of the honeybee (*Apis mellifica*) venom. In this article, we mean Veterinary Apitherapy in its narrow meaning, that is to say, Veterinary Bee Venom Therapy (VBVT).

Ancient writers such as Aristophanes (450–388 BC), Hippocrates (460–377 BC), Galan (131–201 AD), and Charlemagne (742–814 AD) wrote about the medical use of honeybee stings. The Koran refers to bee venom as "liquor wherein is a medicine for men and animals." In 1835 the Reverend Brauns of Germany begun using diluted bee venom in different domestic animals, and later on in 1853, Dr. Constantine Hering introduced the homeopathic use of BVT in the US. About 100 years ago, the physician Dr. Terc of Austria advocated the deliberate use of bee stings for rheumatism. In 1935, Dr. Beck from US introduced apitherapy as we know it today for multiple medical uses.

Bees produce approximately 0.1 mg dried venom per venom sac. It can be introduce intradermally by live bees, or by injection of an extract.

In every 0.1 mg of bee venom there are about 40 different components that are water-soluble. The main anti-inflammatory pharmacologic components are peptides: melittin, apamin, peptide 401, adolapin, and protease inhibitors. Melittin stimulates the hypophyseal-adrenal system and produces cortisone. It is 100 times more potent than hydrocortisone. Melittin also stabilizes the lysosome cell membrane to protect against inflammation. Apamin works like melittin to produce cortisone, and inhibits the complement system, C3, which is involved in inflammation, as well as enhancing nerve transmission. Peptide 401, or MDC peptide, blocks the arachidonic acid and inhibits prostaglandin synthesis. Adolapin inhibits the microsomal cyclo-oxygenase. It is 70 times stronger than indomethacin in animal models, and has analgesic as well as anti-inflammatory properties. It also inhibits platelet lipoxygenase, which involves hydroperoxy-eicotetranonic acid (HPETE), and leukotriene, as well as inhibiting thromboxane (TXA2) and prostacycline (PGI2), which are activated during inflammation. Protease inhibitors inhibit carrageenin, prostaglandin E1, bradykinin, and histamine-induced inflammations; they also inhibit chymotrypsin and leucine-aminopeptidase. Other substances such as Compound X, hyaluronidase, phosphlipase A2, histamine, and mast cell degranulating protein (MSDP), are involving in the inflammatory response of the venom, with the softening of the tissue, and the fascilitation of the flow of the other substances. Finally, there are measurable amounts of neurotransmitters as dopamine, serotonin and norepinephrine. Many reports claim that bee venom has strong antibacterial and antifungal effects.

The clinical uses of apitherapy are numerous: alleviation of many acute or chronic ailments as inflammation and/or degeneration of connective tissue (eg, tendonitis, bursitis, different types of arthritis), osteoarthritis as in canine hip dysplasia, neurologic wasting diseases affecting the limbs (as degenerative myelopathy), neurologic diseases such as peripheral neuritis or radiculitis, chronic pain conditions, autoimmune diseases (eg, lupus), and dermatologic conditions (eg, atopic dermatitis, warts) and scar tissue therapy. Hypogalactica postpartum syndrome in sows is also responsive to VBVT, which is done using bee-acupuncture technique.

Bee venom softens scar tissue and causes scars to fade. Internal scar tissue, such as adhesions resulting from surgery, may also respond to treatment with bee venom.

According to Traditional Chinese Veterinary Medicine (TCVM), we use VBVT for Wei Syndrome (or Wei Bi). Wei syndrome is characterized by weakness of the limbs, which leads to atrophy, flaccid muscles and tendons, and eventual paralysis. This condition generally progresses without pain. We apply VBVT to local and adjacent points, distal and proximal points on the same meridian, and empirical points. The use of VBVT is contraindicated in any pregnant animal, in the presence of any cancerous tumor within 10 cm of the treated site, in patients with any known and demonstrated allergies to honey bee venom, proximity within 10 cm to surgical implant, or in animals on pharmaceuticals that suppress the immune system. It seems that VBVT has reduced benefit in animals with diabetes mellitus.

Side effects of bee venom are generally limited, since the inflammation, swelling, itching etc. are desired effects and usually disappear without further intervention in anywhere from a few to 72 hours. However, the risk of anaphylactic allergic reaction to bee venom is real, and it always wise to have a bee venom sting allergy kit on hand. Fortunately, most "bee" sting allergic reactions are actually to yellow jackets or wasps. Honeybee venom does not necessarily cross-react, and it seems as only 5% of all adverse reactions to insect stinging are related to honeybee stings. Keep in mind that many animals that have had severe local reactions to bee stings, which we consider a positive effect, are incorrectly considered to have allergy to bees.

In the first visit, after evaluating whether VBVT should be applied to the treated animal, as well as contra-indications mentioned before, obtain a written, witnessed informed consent, have with you a preloaded syringe of epinephrine (Bee Sting Kit, Epipen >30 kg animal body weight, Epipen jun <30 kg) and a clinic emergency set-up, press an ice cube against the target site firmly to animal tolerance for 15 to 45 seconds, and apply VBVT to only one site.

The animal must be observed for 10 to 20 minutes. Animal to be excluded from VBVT are those that have systemic reactions such as generalized itching, rashes, short of breath, fever and possible anaphylactic response, or the local reactions are more than erythema greater than 2 cm in diameter and/or wheal greater than 1 cm in diameter. If only local reactions are seen for 20 minutes, the animal's owner is asked to come back for the next therapy session in 72 hours. In a very agitated animal we might consider to put the animal in advance on a light sedative before the application of the sting. Explain to the owner the need in certain cases to use an ice cube locally to calm the animal.

The routine protocol for using VBVT in animals is done by pressing an ice cube firmly against the target site to animal tolerance for 15 to 45 seconds, or infiltrating the area with local anesthetic such as lidocaine 2% without epinephrine to begin with.

Second, extract the bee with long pair of tweezers. Place the posterior aspect of the bee on the desired spot and administer the sting. The bee would then be discarded. Another approach is to eviscerate the bee by pulling the stinger and its attached venom sac from the live bee. The other method is injecting bee venom from a sterile vial (see below).

The number, site, and frequency of stings depend on the treated animal and the clinical problem. A simple tendonitis might just take a few stings, perhaps 2 to 3 at a session for 2 to 5 sessions. A more chronic problem like chronic arthritis can take 2 times per week, several stings at a time, for 1 to 2 months.

Since the immediate effect of bee venom does not last longer than 2 to 3 days, the animal is requested to return after 3 days for further evaluation and therapy.

Never sting on an unresolved previous site. Use a different spot, or wait till the sting has resolved (1 to 3 days). Do not add more than three new sites per visit.

For the injectable bee venom technique, there are sterilized vials on the market. The bee venom can be injected intradermally into the selected points using a 30-gauge needle.

The injectable bee venom dried extract ("Apitox/Apitoxin") containing 1 mg dried venom is diluted in 1 mL 0.9% saline, to give 0.1 mg/0.1 mL = 1 bee sting, or it can be diluted with lidocaine 2% without epinephrine. For every site, we can inject 0.1 mL.

Since we might need to inject many points in one session, it might be a good idea to dilute the 1 mL mother solution into 9 mL saline, and inject into each point 0.2 mL = 0.02 mg of dry bee venom toxin (with lidocaine). Many times we inject the remedy deep into the tissues. For example, for a prolapsed disk we might go 1 cm or more deep into the tissues.

The advantages of the injectable technique include the fact that it is a quantitative procedure, the hypersensitivity issue can be avoided by dilution, and it is a human procedure (as far as collecting venom from bees), available any time and location. A disadvantage is that some of the potency might be lost (the extraction of the bee venom and subsequent desiccation results in a loss of all aromatic substances and about 25% of the greasy acids, and hence a decrease in its medical qualities).

It is important to note that some clinicians dilute the venom homeopathically 3x to 5x, and inject it in the usual way, or into acupuncture points, thus reducing the cost, as well as chances of adverse reactions. In chronic therapy (months), the animal might enter "a reactive phase." The animal's reaction to the venom will be intense. That is a good healing sign, but we might need to add local infiltration of lidocaine to alleviate the animal's discomfort. This phase is very critical time in the entire therapeutic process. At some point things will calm down, and then the therapy can be stopped.

NEUROPATHY TREATED BY BEE VENOM THERAPY

Sagiv Ben-Yakir, BSc, DVM, MRCVS
ORSHINA – The Israeli Institute for Modern Holistic Veterinary Medicine & Sciences
Hod-Hasharon, Israel

A 6-year-old spayed female Golden Retriever was presented to our clinic with acute unilateral left side facial paralysis. The following clinical signs were noted: paralysis of left eyelid; with saliva and food fallen from the same side; nasal philtrum deviated to the normal (right) side; widening of the palpebral fissure with failure to close upon excitation; asymmetry of facial expression, and no signs of involvement of other cranial nerves or other nerve system signs. Otitis media was not observed.

A tentative diagnosis of idiopathic facial paralysis was given, with the probable site of the lesion at the facial nucleus (rostral medulla oblongata of the brain stem) or proximal portion of the facial nerve.

Therapy consisted of application of artificial tears a few times a day to the affected eye and injection of bee venom into acupuncture points.

Twenty micrograms of bee venom with 0.2% lidocaine without epinephrine were injected twice a week for 2 weeks for each of the acupuncture points on the affected side. Two weeks later the dog's facial nerve began to return to normal activity, and dog appreared normal 4 weeks after the start of therapy. Acupuncture points were: ST 02, ST 04, ST 06, SI 18, TH 17, GB 20.

FELINE THROMBOEMBOLISM (SADDLE THROMBUS) TREATED BY MEDICAL LEECHES

Sagiv Ben-Yakir, BSc, DVM, MRCVS
ORSHINA – The Israeli Institute for Modern Holistic
Veterinary Medicine & Sciences
Hod-Hasharon, Israel

A 2-year-old short-haired domestic spayed female cat was presented to our clinic with acute hind limb paralysis with pain in these extremities, lack of a palpable femoral pulse in both legs, cold and blue distal limbs, and lack of bleeding from cut nail beds.

The owner refused to authorize us to perform ancillary tests and asked for a simple and inexpensive therapy. Two medical leeches (*Hirudo medicinalis*) were applied to the each side of the inner side of the thigh close to the abdomen.

Leeches were removed 20 minutes after application. Twenty-four hours later the cat regained almost complete normal walking abilities, was free of pain, and had normal femoral pulses.

This cat was seen and treated in December 2005. The cat has been seen in our clinic a few more times since then and has a normal life. We have had a few similar cases in the past 2 years and all of them responded well to therapy with medical leeches.

EVIDENCE-BASED ACUPUNCTURE

Sagiv Ben-Yakir, BSc, DVM, MRCVS
ORSHINA – The Israeli Institute for Modern Holistic Veterinary Medicine & Sciences
Hod-Hasharon, Israel

During the last few years (1999–2007) we have treated four different cases of canine intracranial blindness (also known as cortical blindness) due to head trauma in hit-by-car situations in our clinic. We used identical protocols for all four cases, and achieved a complete return of vision abilities in a short period of time (within 24 hours). A similar clinical case (a fifth case) was treated at the same period of time in a US-based veterinary clinic with the same protocol given by us and with same clinical result.

The basic protocol that was done:

1. Treat the dog for all other conditions involved in the trauma
2. Diagnosis of intracranial blindness by a certified veterinary ophthalmologist
3. Treat the blindness by routine advised pharmacological methods (steroids, etc.) for 10 days
4. If the dog can not see during and after 10 days, consider performing electro-acupuncture protocol
5. The acupuncture points are ST-01 in a calm dog, but in a more active dog consider ST-02; the second acupuncture point is SI-18. Thus, we are going to use either ST-01 or ST-02 and the second acupuncture point will be SI-18.

ST-01: Cheng Qi, Receiving Tears

- **Location**: In the center of the ventral border of the orbit, between the globe of the eye and the orbital rim (zygomatic arch)
- **Location method**: There is a small notch in the orbital rim. Also, directly below the center of the pupil between the eyeball and infraorbital ridge
- **Characteristics**: Local point that expels exterior and interior Wind from the eye
- **Indications**: Conjunctivitis, atrophy of the optic nerve, retinitis, cataract, any other eye disorder including intracranial blindness, stroke
- **Method of insertion**: Press the eyeball dorsally, and insert the long needle gently to the depth of 0.5–2 cm. along the border of the orbit. This acupoint should be done only by an experienced acupuncturist due to the danger of puncturing the eye!
- **Need a good restraint of the dog.** *For head Blood Stasis therapy might go deep up to 5 cm until you hit the palatine bone.*

ST-02: Si Bai, Four White

- **Location**: Directly below ST-01.
- **Location Method**: Directly below the pupil, ventral to the orbital ridge of the zygomatic bone
- **Characteristics**: Expels exterior and interior Wind from the eye. Relaxes tendons and muscles, smoothes Qi & Blood circulation
- **Indications**: Facial paralysis, conjunctivitis, mandibular myositis, maxillary teeth problems, gingivitis, intracranial blindness, stroke
- **Method of insertion**: Perpendicular insertion 0.5–2 cm, or up to 1 cm if with angular insertion. *For head Blood Stasis therapy might go deep up to 5 cm until you hit the palatine bone*

SI-18: Quanliao, Zygoma Crevice

- **Location**: Directly below the outer eye canthus and below the lower border of zygomatic arch
- **Characteristics:** Expels exterior & interior Wind from the face and eye
- **Indications:** Facial paralysis, trigeminal neuralgia, conjunctivitis, mandibular myositis, maxillary teeth problems, gingivitis, intracranial blindness, stroke
- **Method of insertion:** Perpendicular insertion 0.2-0.5 cm, or up to 1 cm if with angular insertion. *For head Blood Stasis therapy might go deep up to 5 cm till you hit the*

Insert the needles bilaterally, begin with 1 Hz, elevate gradually up to 10 Hz, A/C mode, 5–10 Volts, 6 mA, intermittent mode for 20 minutes.

Evaluation of a successful insertion of the needles is done by evaluation of increased production of eye tears and nasal drops appearance—this can be seen after 10 minutes of stimulation and at levels above 5 Hz. If no drops are seen, change the location of needles. Total time of stimulation is 20 minutes. Re-evaluate the vision ......abilities during the next 48 hours.

If no improvement is seen during this period of time, re-treat the animal. Also, one can stimulate for 20 minutes, stop for 20 minutes, and re-stimulate. This procedure can be re-done a few times in the time period of the mentioned above (48 hours).

So far, we have not found non-responders, but they are expected and will be documented.

Subsequently, an Israeli biomedical company ("Brainsgate") heard about my work and asked me to join the company medical advisor team. Suddenly I had on my team some of the best human medicine Israeli neurologists, neurosurgeons, and neurophysiologists, and I had now hoped to be able to find the anatomic as well as the physiological mechanism behind my work.

The anatomic distribution and functional role of my acupuncture stimulation is well known for the last 80 years in the scientific and medical communities. More and more data is collected every year for the last two decades using up-to-date medical tools (CT, MRI, angiograms, modern histologic techniques, etc).

As I was inserting the needles to these specific locations I stimulate the sphenopalatine ganglion (SPG), also known in dogs as pterygopalatine ganglion. This ganglion is part of the parasympathetic system.

The preganglionic parasympathetic fibers originate in the superior salivatory nucleus and travel first with the facial nerve, and then alone, as the greater superficial petrosal nerve and then the nerve of the pterygopalatine canal or vidian nerve. The latter reaches the SPG, residing in the SPG fossa, where the fibers synapse, or if you wish, in dogs, the pterygopalatine ganglion in the pterygopalatine fossa. The preganglionic neurotransmitter of these fibers is acetylcholine, which acts on nicotinic postganglionic cholinergic receptors. The postganglionic fibers reach the cerbral vasculature, in addition to the lacrimal gland, forehead skin, eye mucosa and nasal mucosa (what explains why upon SPG stimulation we see eye drops and nasal drops). Fibers from each SPG ganglion innervate the ipsilateral hemisphere, and that is why a bilateral stimulation is needed. The stimulation is leading to vasodilatation of the ipsilateral cerebral arteries and augments cerebral perfusion even if initiated within the first 21 days following brain ischemic cases. The increased blood flow to the brain is expected to increase collateral blood flow, bypassing the blocked section of the cerebral artery and bringing oxygen to damaged areas of the brain. The neurotransmitters released by the postganglionic fibers include nitric oxide (NO), vasoactive intestinal polypeptide (VIP), and acetylcholine as well as others.

The role of nitric oxide is not only to reduce the infarct size after local ischemia, but also to promote neurogenesis in the adult brain and promote rehabilitation.

An additional finding is that upon stimulation of the SPG we temporarily increase the permeability of the blood–brain barrier.

Another point that should be mentioned is that there are many intraocular projections/branches from SPG, and it means that even improper location/insertion of the needles might have achieved a clinical result.

CONCLUSION

in the last 80 years, a great deal of scientific and medical work has been done regarding the anatomy and physiology of our specific protocol. According to Thomas Kuhn in his book, *The Structure of Scientific Revolution,* one can see that most of CAVM has different paradigms from the modern western medicine. It is important to understand the nature of paradigms, including the appropriateness of assessing one by the other.

No paradigm is a complete one, being unable to answer all the questions that can be asked of it. Paradigm is not associated with truth; it involves methodologic approach towards problems. Different paradigms have different frames of references, and one paradigm cannot be translated into another. For example, Newton's Laws are not simply a special case of Einstein's theories of relativity, or can we translate the Chinese term "Qi" into "Energy" of the western world? Qi (like Yin & Yang) is a fundamental and complex concept which cannot be understood without taking into account the totality of the theoretical foundation and practice of Chinese medicine in addition to the Chinese worldview. Meridians are referred in western terms as two-dimensional passageways, but in TCM they are looked as three-dimensional passageways through which Qi and Blood flow at different levels of the body. Is it inappropriate to refer to the channels by using two-dimensional terms? There are many other fundamental examples.

Because of the incommensurability of paradigms, any CAVM practiced its original way cannot be the same as its biomedical version – they must stay two separate ways. If the biomedical paradigm is adopted, it will have its characteristics—materialistic, mechanistic, reductionist, linear-causal, and deterministic, and in short, "Yin and Yang do not exist" will be unavoidable.

Also, the questions and answers are different in the different paradigms. A CAVM clinician will recognizes conditions that are hard to diagnose in biomedical terms, and if the paradigm will be changed, this ability will be lost forever. We should insist that our own paradigm be given full recognition and acceptance.

A NOVEL APPROACH TO VETERINARY DERMATOLOGY

Sagiv Ben-Yakir, BSc, DVM, MRCVS
ORSHINA – The Israeli Institute for Modern Holistic Veterinary Medicine & Sciences
Hod-Hasharon, Israel

Chinese physicians working from the beginning of the Ming dynasty (1368–1644 C.E.) through the Qing dynasty (1644–1911 C.E.) developed what became known as the pattern of four levels (*wei-qi-ying-xue bian-zheng*). Taking from the *Nei Jing* they described four sequential physiological entities/scenes; each one of them represents a different distinct depth of body's pathology.

The first level, called the **pattern of Wei Qi** (wei-fen-zheng), occurs at the first depth of the body, from the level above the skin (fur coat, flora on the skin, sweat, sebum, IgA from the animal's saliva, etc.) and extends inward through the stratum corneum, stratum granulosum, and to the upper part of the stratum spinosum of the epidermis.

The second level, called the **pattern of Qi** (qi-fen-zheng), occurs at the second depth of the body, from the lower part of the stratum spinosum to the basal layer (stratum basale) of the epidermis, referred to collectively as the stratum germinativum or Malpighian layer.

The third level, called the **pattern of Ying** (ying-fen-zheng), occurs at the outer two thirds of the dermis. The word ying describes the Nutritive aspect of Qi that is associated with Blood and mainly with extra-cellular fluid.

The fourth level, called the **pattern of Xue** (Blood) (xue-fen-zheng), is the final and deepest of the four levels. It is the lower part of the dermis, in the lower blood plexuses and in the hypodermis.

According to this specific concept, one should look on animal's skin and asks: "At what level the lesion can be found?"

Acute moist dermatitis due to flea bites ("hot spot") might be in the Wei Qi level. When one is presented with chronic ulcerative dermatitis due to an immunological condition such as discoid lupus erythematousus, one can see that the lesion is deep into the Xue level. In cases of lichenification and hyperpigmentation, the lesion might be in the Ying level.

The answer can be found by simple observation without any specific advanced tools, or one can use histological preparations or other advanced methods to assist in making the determination of the lesion's location.

By making the determination of the lesion location we are making our diagnostic process easier. It will also allow us to set up our therapeutic goals; for example, for lichenification and hyperpigmentation due to a lesion at the Ying level one should nourish the Yin, etc.

We will also be able to give a prognosis and realistic timetable for healing: the healing time for a Wei Qi level problem will be a few days and prognosis is excellent. If the lesion is deeper, the healing time will be longer—from weeks to months—and the prognosis for complete cure also worsens when the process is deeper.

One will also have better understanding of the pathology and pathogenesis of the pattern.

As part of this new approach we are going to look for other acupuncture points compared to what we used in the past (for example, Blood-related points for Xue level issues, as BL 17, LU 9, etc.) and new herbal formulas (for example,. for Ying & Xue levels issues, formulas for clearing Heat from Ying level, invigorating Blood, etc.).

One can adopt the four levels concept regarding dermatological conditions and work up clinical cases successfully. We can expand our abilities by adding the six stages concept to the working-up scheme of skin conditions.

Zhang Zhong-jing, one of the greatest physicians in Chinese history, developed in his classic book *Shang-han Lun* ("Discussion of Cold-induced Disorders", written around 220 C.E.) the idea of six stages pattern (*liu-jing bian-zheng*). The ideological background is taken from the *Nei Jing* that describes six disease stages. The six stages presented in his book comprise a series of patterns that map out the course of diseases.

Dr. Zhang suggests that diseases begin with the first stage and proceed in sequence to the sixth stage; however, a disease can go straight to any stage, skip stages, or even move in a reverse way.

The first stage is called ***Tai Yang*** (Small Intestine and Bladder stage). Second, the disease might enter either ***Yang Ming*** (Large Intestine and Stomach) or the ***Shao Yang*** (Triple Heater and Gall Bladder) stage.

Yang Ming will mark the internal development of the disease.

Shao Yang is known as a half-Exterior/half-Interior pattern, and should be therefore before *Yang Ming*; however, based on the original *Nei Jing* concept it appears after *Yang Ming*.

These first three stages, ***Tai Yang, Yang Ming,*** and ***Shao Yang***, are patterns of Excess. The next three stages are patterns of Deficiency and Interiority.

The fourth stage is ***Tai Yin*** (Lung and Spleen), the fifth stage is ***Shao Yin*** (Heart and Kidney), and the sixth stage is ***Jue Yin*** (Liver and Pericardium).

It is common in dermatology to place the four levels and six stages one beside the other, which helps us to expand our diagnostic and therapeutic abilities (Table 1). This step directs the clinician not only to a better understanding of the process involved, but allows for a better selection of goals, acupuncture points, and herbal remedies.

To improve our abilities in the application of traditional Chinese veterinary medicine (TCVM) herbal remedies to animals I would like to introduce another concept, the third and last one in this article—transdermal herbal gel or foam. My suggestion to all of you – by putting your Chinese herbal remedies in transdermal gel or foam you are going to dramatically increase your clinical success rate.

Table 1. Pattern of the Four Levels and the Six Stages of Disease

Four Levels	Six Stages
Wei Qi Level	Tai Yang (SI+BL); Yang Ming (LI+ST)
Qi Level	Shao Yang (TH+GB); Tai Yin (LU+SP)
Ying Level	Tai Yin (LU+SP)
Xue Level	Shao Yin (HT+KID); Jue Yin (LIV+PC)

Advantages of using transdermal gels or foam include:

- No need to give pills, capsules, or tinctures, thus avoiding fights with the treated animal, or causing mental or physical trauma to the treated animal or the owner
- Good cosmetic qualities, as there is no visibility, no smell, and no residues on the skin, avoiding sticky or greasy feeling, and avoiding rubbing on carpets, furniture, clothes, etc.
- Potential for in-clinic manufacturing
- Ability to apply remedy to large surface area
- No lag time
- Cost effective
- Less irritation associated with occlusion or reaction to adhesives
- Absorption is done within less than one minute – so no need for neck collars or other protective measures to prevent the animal from licking or rubbing the remedy
- Excellent skin tolerability and nontoxic
- Uniform absorption
- The remedy forms a reservoir in the epidermis and enables once-a-day application
- The high water content provides good moisturizing properties

Disadvantages of using transdermal gels or foam include:

- Not appropriate if remedy needs activation in the gut
- Owner needs to put gloves on to apply or have a topical syringe

Note: Gels should be protected from sunlight and heat, and kept out of reach of children and animals.

HEMOACUPUNCTURE, OR THE THERAPY THAT STICKS

Sagiv Ben-Yakir, BSc, DVM, MRCVS
"ORSHINA" – The Israeli Institute for Modern Holistic
Veterinary Medicine & Sciences
Hod-Hasharon, Israel

In the last few years there has been a tendency in many parts of the international veterinary acupuncture community to work up a therapeutic plan using a Deficiency pattern. Many are citing from the *Nei Jing*: "The normal doctor treats thousands of symptoms (by using local and symptomatic treatment), the good doctor treats the underlying Excess, but the superior doctor treats the underlying Deficiency." But when one is dealing with Blood Stasis/Stagnation one should keep in mind also other cites from the same book:

- "If there is a stagnation it should be resolved by bloodletting before acupuncture and/or moxibustion."
- "If stagnant blood is not moved, new blood can not engendered."
- "Disease will not develop into a critical condition if the Blood keeps flowing."

WHAT ARE THE TCVM THEORIES AND MECHANISMS BEHIND THE NECESSITIES AND THE EFFECTS OF BLOODLETTING?

Direct Effects:

- Frees the flow of Qi
- Resolves Blood Stasis
- Clears Vacuity and Replete Heat
- Clears Blood-Heat
- Releases toxicity

Indirect Effects:

- Supplements Qi
- Nourishes and regenerate Blood
- Extinguishes Wind
- Calms the Shen
- Promotes sleep

History and Clinical Signs of Blood Stasis:

- History of external injury
- History of reproductive problems
- History of psycho-emotional disorder
- Enduring disease
- Variable energy level, tiredness better w/activity or movement, depression, moodiness, sighingLocalized sharp and constant stabbing painPain worse at night
- Pain's arc
- Itching with discolored skin patches, lesions might be chronic and raised, also ulcerated, coat is withered and yellowish, nails withered and/or falling off, peeling of abdominal skinHard, well-defined, immobile or fixed, possibly tender or painful lumps or masses, including organ enlargement, lumps/masses that may bleedLegs tremors, up to numbness or hemiplegia
- Purplish/blue lips
- Bloody stool/urine with bleeding of dark purple/brown/black clotted blood
- Pulse – choppy, regularly interrupted, deep or fine
- Tongue – purple spots/patches on tongue up to dark, brownish or engorged red tongue
- Purple blood vessels in the eye's sclera, bluish eyelids

Contraindications for Bloodletting Therapy:

- Coagulopathy or animal on anticoagulant therapy
- Anemia and/or low blood pressure
- Last stages of malignant tumor
- Pregnant animal
- Bleeding in estrus time

What Points Do We Bleed?

- Local & painful points
- Distal & proximal points of the affected meridian
- Jing Well/Ting points for specific problems according to the affected zang fu organ/meridian
- Treat LIVER points (LIV-02/03/14), BL-18, GB-34 to move Qi & Blood
- Treat HEART points to benefit Heart function of controlling Blood
- Empirical points as BL-17
- Around the ears pts (for head issues)
- GV-14 for pink eye, conjunctivitis, retinal atrophy
- GB-21, TH-15 for stiff neck/shoulders
- LI-15, TH-14 head-skin disorders
- Between shoulder blades for chronic gastritis & respiratory issues as asthma & bronchitis
- Uro-genital issues or mastitis – inguinal area

WHAT ARE THE TOOLS TO BE USED?

Medical Leeches *(Hirudo medicinalis)*

Why? Medical leeches are the best equipped creature on our globe to locate a point in Excess, especially a point with Blood Stasis/Stagnation, and that due to the fact that all their existence is about locating this point in Excess.

Additional benefits will be that we can work our way back in the Ko cycle, and use the leeches as a diagnostic tool for finding the Zang-Fu organ or meridian in Deficiency, and treat these points later. Also, due to the bacteriostatic and anesthetic abilities of the medical leeches, we can apply them to an acupuncture point or a tissue to be treated that is infectious and heavily contaminated area, and also a very painful area.

The use of medical leeches (Veterinary hirudotherapy, or VHT) is one of the oldest recorded veterinary medical treatments. The routine practice led patients to refer to their physicians as "leeches" (see current or old editions of Oxford Dictionary).

In the 20th century there was a marked decline in the use of medical leeches. Toward the end of the 20th century and at the beginning of the 21st century, there has been a medical shift to the re-use of medical leeches, and on June 28, 2004, the FDA cleared medicinal leeches for marketing as a medical tool. In November 2004, the journal *Nature* reported that 80% of Britain's 62 plastic-surgery units had used leeches postoperatively in the past 5 years. Leeches (*Hirudinea*) are slippery hermaphrodite bloodsucking worms with segmented bodies. They belong to the same large classification of worms as earthworms and certain oceanic worms (Annelids). Leeches can be found in freshwater lakes, ponds, or rivers with body size from 0.2 inch (5 mm) to nearly 18 inches (45 cm). Leeches consume the blood of a wide variety of animal hosts, ranging from fish to humans. There are over 650 known species of leeches, but the leech most commonly used is the European Medical Leech (*Hirudo medicinalis*). The leech has two characteristic suckers at both ends that attach jointly to the tissue while feeding. The mouth has three sharp jaws that leave a Y-shaped bite with some 100 tiny teeth on each jaw. A leech is an efficient bloodsucker. When attached, it can suck 5 mL of blood, an amount that is six to ten times its body weight, usually within 10 to 30 minutes. After its blood meal the leech falls from the tissue.

As the worm bites, it injects a complex cocktail of proteins into the host through its saliva, which are responsible for the therapeutic effects as well. The saliva contains Hirudin, a potent anticoagulant that consists of 65 amino acids. Hirudin inhibits the conversion of fibrinogen to fibrin by inhibiting thrombin & preventing blood from clotting. Hirudin also inhibits platelets aggregation. Hirudin works in conjunction with a vasodilator, one that increases the diameter of blood vessels by relaxing the smooth muscle of the blood vessels, to widen the diameter of the vessel and increase the flow of blood and by that promotes blood flow. The leech's vasodilator is a histamine-like substance. The effectiveness of this therapy is not simply due to enhanced blood flow, but because bleeding from a bite may continue as long as 10 hours, relieving tissue congestion mainly due to venous insufficiency, in areas where arterial flow is maintained but venous return is severely compromised, until collateral circulation reestablishes sufficient venous return in 4 to 5 days.

The frequency of the therapeutic sessions can vary from once for a sole day up to a few consecutive days to once every couple of weeks. Destabilase and hyaluronidase help breaking apart any fibrin fibers and local connective tissue and by that facilitate continual blood oozing from the leech's wound. Leech saliva contains a local morphine-like analgesic substance, allowing a painless attachment and feeding. An animal bitten by a leech may not even be aware of it until afterwards. Leech's saliva contains natural bacteriostatic component, as well as some regenerating and immunomodulatory substances. The saliva contains at least one anti-inflammatory molecule called leech-derived tryptase inhibitor.

What are the classical/western uses of medicinal leeches? Medicinal leeches applied to congested or inflamed parts of the animal body for over 3,500 years. They were used for engorged blood vessels as in acute equine laminitis, canine aural hematoma, swollen testicles, laryngitis, canine prolapsed rectum or bovine prolapsed uterus and inflamed vulva. Today, leeches are used also in reconstructive surgery on swollen faces, limbs, and digits following successful arterial re-vascularization but limited venous repair. Leeches are also used in the treatment of such disorders as inflammation and peripheral venous and arterial diseases as in cat's saddle thrombus. Leeches are also used to treat inflammatory and traumatic processes such as keratitis, chorioretinitis, periorbital hematoma, subretinal hemorrhage, glaucoma and cataract.

Leeches are being used to treat inflammatory diseases of the ear, nose and throat such as acute and chronic otitis, sinusitis, aural hematoma, and laryngitis, and to treat clinical forms of dermatitis and dermatosis (eg, eczema, paronychia, acral lick dermatitis). Leeches can be used to treat acute and chronic inflammatory immune-associated oral mucosa and peridontium lesions as in FIV-positive cats with severe stomatitis and gingivitis, diseases of the salivary glands as sialadenitis and sialoadenosis. Furthermore, leeches are used to treat inflammatory conditions of the urogenital tract as endometritis, dysfunction and injuries of the genital organs in postoperative rehabilitation.

Leeches are used to rehabilitate animals with postpartum pyo-septic complications. Hirudotherapy was also found to be effective in healing intractable and non-granulating wound or ulcers, especially in elderly and immunocompromised animals.

Leeching has been used as well for treating cats with polycythemia vera, or to reduce scrotal edema post-castration procedure in adult dogs. Recent studies suggest that leeches can lessen the pain of osteoarthritis and restore lost mobility as in canine hip dysplasia cases or knee osteoarthritis. Keep in mind that osteoarthritis is more than a disease of joint's wear and tear, it is also a vascular disorder. Small clots can occur in the blood vessels supplying bone and joint, and starve the tissue for oxygen. Chemicals that thin the blood and break clots apart could ease animal's misery as well as assisting in regeneration.

Once leech therapy is chosen, the clinician contacts one of many companies now spread all over the country to place an order for *Hirudo medicinalis*.

The leeches will come a container with non-chlorinated water. Some companies will add some salts or gels for better housing of the leeches. To store leeches in the clinic, use non-chlorinated water. No more than 50 leeches should be placed in a 2-gallon container. A tight-fitting lid is a necessity when housing the leeches to avoid escape. Lid perforations for air venting are advised. Leeches should be kept cool, not above 68°F (20°C), and avoid direct sunlight. Leeches can be kept for up to 3 months in un-fed condition. Change of suitable water is needed once a week.

Before applying the leeches, the area to be treated should be cleansed with clean non-chlorinated water. Remove any traces of povidone-iodine (Betadine) or any other skin preps. These traces may discourage the leech from attaching. Leeches should be applied in adequate numbers to the general area of maximal congestion or other treated area/tissue. One or two leeches may be sufficient to treat an area of 5 square cm. Move the container of leeches close to the patient. Wearing non-sterile gloves, take a long pair of non-toothed forceps in one hand and carefully lift the lid of the container. Be prepared to see some leeches clinging to the sides and even the lid of the container. Try to quickly but gently grasp a leech and remove it from the container. Leeches are very elastic and slippery and this combination makes them difficult to carry. The head (or biting end) of the animal can be recognized by its searching movements, while the tail end is used mostly as a sucker for attachment. One can use the barrel of a 5-mL syringe to transport a leech from the container. Usually attachment occurs quickly; however, if the leech is reluctant to bite, make a small needle prick on the skin to produce a tiny droplet of blood, or try another leech. If persistent resistance to feeding occurs it is often indicative of poor arterial supply (bad sign for the treated tissue) or the presence of some residual materials on the animal's skin. To prevent leech wandering, form a barrier by cutting a 1 cm hole in the middle of a dampened gauze square and locating the hole in close contact with the area to be treated. Alternatively, a transparent, non-permeable dressing material with a hole cut into it can be used. The leech will usually stay in the same place until feeding ends, which is about 10 to 30 minutes. It is important not to disturb the leeches during feeding as this could result in premature detachment and regurgitation of the leech stomach contents into the bite wound. The bite will continue to ooze for an average of 3 to 6 hours.

Used leeches should be put in a container with the treated animal's name on it and the date of use for future therapeutic sessions on the same patient with the same leeches.

Remember, weigh the leeches after the treatment to help assess the patient's blood loss, as well as weighing the gauzes used during and after the procedure. The treated animals usually do not care much about the use of leeches since the procedure is a nonpainful one. For use in an animal's mouth to treat stomatitis or similar conditions, we do a short isoflurane anesthetic regime.

Hirudo medicinalis has an obligatory symbiotic relationship with a bacterium *Aeromonas hydrophila* (*Pseudomonas hirudinis*). The bacteria breaks RBC hemoglobin, and also secretes antibiotics to prevent other bacteria growth, as well as production of needed vitamins (as B vitamins) to the leech. The bacteria is not present in the mouth parts of the leeches, but deep in its gut. Nevertheless, if we disturb the leeches during feeding, this could result in regurgitation of the leech stomach contents into the bite wound with bacteria. If this happens, the animal should be given antibiotics (as new quinolones) for 3 days. Some veterinarians are giving the leech itself antibiotic prior to the therapy. Used leeches should not be returned to the un-fed leech container, because leeches may feed off of each other. They can be saved for re-use on the same patient, although they may not be ready for another blood meal for a month or so. Leeches that are saved for re-use must be kept in a container labeled with the patient's information and date of use. Do not dispose any live leeches into any sinks due to possible environmental contamination. Some clinicians dispose of leeches after a single use. Leeches should be disposed off by placing them in a container of 8% alcohol to narcotize them, then into 70% alcohol for 5 minutes to kill them, and then they can be disposed as for other infectious waste. In our clinic we keep them for 3 months for possible future use on the same patient; if this is not needed, we put "these hard-working animals" in a huge tank in which they can grow old and live out their entire 20 years.

Families are often repulsed by the idea of VHT. Good client education is needed. Explain to the family that leeches are an accepted medical treatment all over the country for the last few years, and approved by the FDA, with proven history of success.

PROLOTHERAPY – A GREAT CAVM METHOD TO SOLVE MUSCULOSKELTAL PROBLEMS

Sagiv Ben-Yakir BSc, DVM, MRCVS
"ORSHINA" – The Israeli Institute for Modern Holistic Veterinary Medicine & Sciences
Hod-Hasharon, Israel

Prolotherapy is defined by *Webster's Third New International Dictionary* as "the rehabilitation of incompetent structure, such as ligaments or tendons, by the induced proliferation of new cells" that is done for the purpose of strengthening weakened connective tissue and alleviating musculoskeletal pain. The term derived from the word *prolo*, short for proliferation, as the therapy is intended to proliferate tissue growth in the damaged area.

Prolotherapy is also called "proliferation therapy" and "regenerative injection therapy" (RIT).

Prolotherapy can be distinguished from sclerotherapy, the use of injections of caustics into the veins, in vascular surgery and dermatology, to remove varicose veins and other vascular irregularities.

In prolotherapy we inject solutions into the area where connective tissue has been weakened or damaged through injury or strain. Many solutions are used, including dextrose, lidocaine, a combination of both, the animal's own blood, added growth factors, phenol, glycerine, sodium morrhuate, and others.

The injection is given into joint capsules or where tendon connects to bone. Many points may require injection. The Injected solution causes the body to heal itself through the process of inflammation and repair. In the case of weakened or torn connective tissue, induced inflammation and release of growth factor at the site of injury may result in a 30% to 40% strengthening of the attachment points.

Prolotherapy treatment sessions are generally given every 2 to 6 weeks. Many patients receive treatment at less and less frequent intervals until treatments are required only every several years, if at all. Prolotherapy is often used as an alternative to an invasive and expensive surgery.

In our practice we are using 15% dextrose as our injection solution into ligaments. Added to the solution is a small amount of lidocaine without epinephrine. We take 1 mL of lidocaine 2%, 3 mL of 50% dextrose, and 6 mL of sterile water. We shave the area to be injected, scrub it with Septal Scrub (4% chlorhexidine), wash it with alcohol 70%, and finish up the preparation by putting PVP Iodine 10% on the area. The injection is done with 27- to 30-gauge needle and it is important to inject small webs into the ligaments rather than one or two large amounts. In most animals, this can be done without sedation or anesthesia. In some active animals, sedation or short-time anesthesia is needed.

For a successful therapy, one should know the anatomy of the region to be treated. We know that many acupuncture points are located at the junction of ligaments to bones, or in ligaments; therefore, it is easier to a qualified animal acupuncturist to locate the proper sites for injections, and be able to manipulate the small needles.

Usually there is some local pain and swelling for a few weeks, and great improvement is achieved after this period of time. In the first few weeks one can give nonsteroidal anti-inflammatory drugs (NSAIDs) on and off as needed, but not as a routine protocol—after all, we are looking for the inflammatory response to boost in.

Limited physical activity is advised (eg, no jumping), but the owner should be instructed to do manual therapy two to three times a day for the first few months. In some animals "a tune-up" injection is needed after 6 or 12 months.

Different solutions can be injected in prolotherapy:

- Osmotic proliferants that by their higher osmotic pressure induce the process of inflammation and healing (eg, dextrose, which is water-soluble and is not stored in the body but excreted out)
- Irritants are substances that alter the surface of the cells and induce the process (eg, phenol)
- Particulates such as pumice flour or the animal's own blood attract macrophages and induce the process of prolotherapy
- Chemotactics that directly attract immune system cells to the area (eg, sodium morrhuate)
- Growth factors

PROLOTHERAPY'S MECHANISM OF ACTION

The mechanism of action is complex and multifaceted. Six identified components include:

- The mechanical transection of cells and matrix induced by the needle, causes cellular damage, stimulating an inflammatory cascade.
- Compression of cells by the extracellular volume of the injected solution stimulates intracellular growth factors.
- Chemomodulation of collagen through inflammatory proliferative, regenerative/reparative responses is induced by the chemical properties of the proliferants and mediated by cytokines and multiple growth factors.
- Chemoneuromodulation of peripheral nociceptors and antidromic, orthodromic, sympathetic and axon reflex transmission.
- Modulation of local hemodynamics with changes in intraosseous pressure leading to the reduction of pain. Empirical observations suggest that a dextrose/lidocaine combination has a much more prolonged action than lidocaine alone.
- A temporary repetitive stabilization of the painful hypermobile joints, induced by the inflammatory response to the proliferants, provides a better environment for regeneration and repair of affected ligaments and tendons.

Injections of irritant solutions were performed in the late 1800s to repair hernias and in the early 1900s for jaw pain due to temporomandibular joint laxity. Dr. George S. Hackett, MD, developed the technique of prolotherapy in the 1940s. He claimed in his book "Ligaments and Tendons Relaxation Treated by Prolotherapy" (1958) that he cured 90% of 656 patients. At that time, he used a fatty acids mixture as an injection solution to induce inflammatory reaction. Nowadays we are using a simple dextrose solution diluted with local anesthetic such as lidocaine to achieve the same results without the possible risks (eg, shock). Dr. Hackett found that the injected tendons increased in diameter by 40% after prolotherapy, and histologic exams showed no destruction of nerves or blood vessels and no scarring, which is a chaotic matrix of collagen fibers. The ligaments and tendons produced after prolotherapy appear much the same as normal tissue, except that they are thicker, stronger, and contain fibers of varying thickness with normal histologic organization. There is an increase in collagen-producing fibroblasts, and the ligament's orientation and internal organization is linear.

Dr. Gustav A. Hemwall, MD, is one of Hackett's most famous students, beginning his studies and treatments in the 1950s and continuing until the mid 1990s. In his study of almost 10,000 cases he reported from 75% to 90% successful results, some of which were for longstanding problems that have been resistant to other treatments.

If one is wondering what might happen in years to come with complementary and alternative veterinary medicine, the following story is of interest. Dr. Everett Koop, MD, US Surgeon General, had a severe pain followed by almost a complete paralysis of his right hand during 1980. Since no therapy was able to resolve his condition, he approached Dr. Hemwall. Dr. Hemwall treated Dr. Koop by prolotherapy injections into his neck, and the medical issue was solved in a short time successfully. Dr. Koop studied more about the prolotherapy method, endorsed it, and nowadays prolotherapy is considered as subspecialty of the American Association of Orthopedic Medicine.

INDICATIONS FOR VETERINARY PROLOTHERAPY

- Chronic pain from ligaments or tendons secondary to sprains or strains
- Pain from overuse or occupational conditions (eg, dog/horse racing) known as "repetitive motion disorders"
- Chronic postural pain of the cervical, thoracic, lumbar, and lumbosacral regions.
- Painful recurrent somatic dysfunctions secondary to ligament laxity that improves temporarily with manipulation
- Painful hypermobility and subluxation at given peripheral or spinal articulation(s) or mobile segment(s) accompanied by a restricted range of motion at reciprocal segment(s)
- Thoracic and lumbar vertebral compression fractures with a wedge deformity that exert additional stress on the posterior ligamento-tendinous complex
- Recurrent painful subluxations of ribs at the costotransverse, costovertebral, and/or costosternal articulations
- Osteoarthritis of axial and peripheral joints, spondylosis, spondylolysis, and spondylolisthesis
- Painful cervical, thoracic, lumbar, lumbosacral and sacroiliac instability secondary to ligament laxity
- Intolerance to NSAIDs, steroids or opiates.
- Prolotherapy may be the treatment of choice if the patient fails to improve after physical therapy, chiropractic or osteopathic manipulations, steroid injections or radiofrequency denervation, or surgical interventions in the aforementioned conditions, or if such modalities are contraindicated.

SYNDROMES AND DIAGNOSTIC ENTITIES CAUSED BY LIGAMENT AND TENDON PATHOLOGY THAT HAVE BEEN SUCCESSFULLY TREATED WITH PROLOTHERAPY

- Cervicocranial syndrome (cervicogenic pain, secondary to ligament sprain and laxity, atlanto-axial and atlanto-occipital joint sprains, mid cervical zygoapophyseal sprains).
- Temporomandibular pain and muscle dysfunction syndrome
- Torticollis
- Cervical segmental dysfunctions
- Cervicobrachial syndrome (shoulder/neck pain)
- Hyperextension/hyperflexion injury syndromes
- Cervical, thoracic and lumbar sprain/strain syndrome
- Costochondritis/chondrosis
- Recurrent shoulder dislocations
- Lumbar instability
- Lumbar spondylolysis
- Sacroiliac joint pain
- Sacrococcygeal joint pain
- Myofascial pain syndromes
- Ankylosing spondylitis
- Shoulder, stifle, foot and ankle chronic sprain, instability, laxity of ligaments

Some examples include cruciate ligament laxity or partial rupture, patellar subluxation/luxations, stifle collateral ligament injury, tarsocrural luxations, other carpal and tarsal luxations, temporomandibular joint luxation, shoulder, elbow, carpal, and sacro-iliac luxation, and wobbler's syndrome.

CONTRAINDICATIONS

- Allergy to anesthetic or proliferant solutions or their ingredients such as dextrose, sodium morrhuate, or phenol
- Acute non-reduced subluxations or dislocations
- Acute arthritis (septic or post-traumatic with hemarthrosis)
- Acute bursitis or tendonitis
- Capsular pattern shoulder and hip designating acute arthritis accompanied by tendinitis

- Acute gout or rheumatoid arthritis
- Recent onset of a progressive neurologic deficit including but not limited to (severe intractable cephalgia, unilaterally dilated pupil, bladder dysfunction, bowel incontinence)
- Requests for a large quantity of sedation and/or narcotics before and after treatment
- Paraspinal neoplastic lesions involving the musculature and osseous structures
- Severe exacerbation of pain or lack of improvement after local anesthetic blocks
- Relative contraindications: central spinal canal, lateral recess and neural foraminal stenosis

In summary, prolotherapy is a safe and effective medical method in which mildly irritating solution is injected into ligaments, tendons, or their insertions to bones or muscles, causing a mild inflammatory response which stimulates healing. The result is a thicker, stronger, well-organized tendon/ligament, a less sensitive one, that decreases local and remote structure stresses. Over 75% to 90% of patients treated with prolotherapy get significant improvement or cure.

HOMOTOXICOLOGY – AN INTRODUCTION OF THE MODERN VETERINARY HOMEOPATHY INTO THE DAILY ACTIVITIES OF A BUSY VETERINARY CLINIC

Sagiv Ben-Yakir, BSc, DVM, MRCVS
"ORSHINA" – The Israeli Institute for Modern Holistic
Veterinary Medicine & Sciences
Hod-Hasharon, Israel

The young German physician, Dr. Hans-Heinrich Reckeweg, is just graduating out of the well-known human medicine college at Bonn University. The year is 1930, a hard time in Germany, economically as well as politically, but nevertheless he opens his own clinic in the capital of the country, Berlin. But more than this, he begins practicing his own medical method—Homotoxicology. He makes following declaration: "I am writing and performing something that is quite important to medicine. It will take a long time until it will be fully recognized." He began talking about the influence of environmental pollutants on his patients' health, and keep it mind—the year is just 1930, long before the 1960s when we begun our environmental awareness. During the first years he was preparing (with his family) all the remedies needed for his practice, but more and more German physicians begun using his concept, so in order to meet the increasing demands he established in 1935 a family pharmaceutical company by the name "Heel" in order to supply the needs. (Heel is an acronym of four Latin words: *herba est ex luce,* or plants come from light). This young physician, only 25 years old, facing an unstable period of his own country, somehow found a peaceful mind, the courage to establish his own medical concept, fully developing it in his own clinic and at the center of the country, attracting so many admirers, and established a pharmaceutical company to support his own agenda. As it turned out, the young Hans-Heinrich Reckeweg was a son of a well-known family, all practicing conventional medicine. His own father suffered a serious kidney disease, and was cured by a homeopath. The family then began to study homeopathy and to practice it. In homeopathy there is a great awareness for external influences as part of the daily routine of diagnostic procedures. So it was no wonder that the young Reckeweg could develop his own thinking about the influences of environmental pollutants on his patients, and enjoy his family's support for his ideas. As Reckeweg claimed, many human and animal diseases seemed to be caused by exposure to toxins, both of external and internal nature (exogenous toxins such as viruses, bacteria, fungi, heat, cold, dampness, dryness, heavy metals, fumes, etc., or endogenous toxins such as emotions, different metabolites as free radicals, urea, etc.). He termed this principle *Homotoxicology*, that is, the study of toxins on humans. The presence of such toxins was undeniable in view of the increasingly polluted environment and widespread damaging lifestyle choices. Homotoxicolgy is a branch of medicine that seeks to identify the toxins in the body, then aids the natural defense mechanisms in clearing the toxins out of the body, thereby rendering the fluids, the matrix (connective tissue), and cells free of toxic debris. Dr. Reckeweg's theory says that "the organism is a flow-system attempting to maintain the equilibrium of this flow. The biological flow can be disturbed by substances (toxins) that tend to damage the organism. The organism attempts to defend itself against this threat: this battle of the organism against toxins is the fundamental definition of a disease in homtoxicolgy. Diseases are the expressions of the organism's battle against toxins, its attempt to counteract and expel them, or the expression of an organism's efforts to compensate for toxic damage which it has sustained," and we might say Homotoxicosis = Disease.

The disease goes through a certain evolution: in the **first phase** (out of six), the toxins excreted through physiological orifices by increasing production of normal bodily fluids (as tears, saliva, mucus, sweating, urination, diarrhea, sneezing, etc). This first phase is named **"The Excretions Phase."** This is almost a normal-natural situation known to all of us, manifestations of increased physiological excretion mechanisms, as for example when someone is puffing a cigarette smoke in our face (an external toxin), or when we have a deep emotiom (an internal toxin), and we begin tearing or coughing.

The **second phase**, **"The inflammation Phase,"** is done by the body after its unsuccessful attempt to expel toxins in the first phase. The organism is aiding the inflammatory system locally or systemically to fight the toxins—for example, rhinitis, laryngitis, colitis, etc. This phase is marked by exudative inflammation. So far the fight is centered in the body fluids, so these two phases ....have a common name, **Humoral Phases**. In these clinical situations the intracellular systems are not disturbed. When the toxins can not be "burned out," they must be stocked in the connective tissue & adipose tissue (the matrix). At first, the toxins are deposited in the mesh of the extracellular matrix, as in the formation of cysts, mucous membrane polyps, prostate gland hypertrophy, lipoma, warts, kidney, bladder or gallstones, etc. The organism initializes attempts to excrete these toxins again and again, which causes symptoms to flare up. This **third phase** is named "**Deposition Phase.**" The toxins are not integrated into the structural components of the matrix, simple excretion of the toxins is possible, and up to this stage of the disease's evolution the treatment is easier, and its outcome is good to very good. In homotoxicolgy we mark the good prognosis by putting an imaginary boundary between these phases to the next phases, and we name it "**The Biological Division,"** as further on, a spontaneous endogenic excretion of the toxins is impeded.

As the toxins become an integral part of the matrix, along with changes in its structural and functional components, the body moves to the next, **fourth stage**, **"The Impregnation Phase."** This time the toxins become integral part of the matrix, they cause structural and functional changes in the matrix, more clinical signs are seen, and primordial damages to the cells in the organ occur. In this phase the disease may remain latent and later give rise to a locus minoris resistentiae, site of diminished resistance—for example, chronic rheumatoid arthritis, COPD, autoimmune diseases, asthma, IBD, etc.

Since in the third and the fourth phases the toxins are deposited in the matrix, the combined name for these two stages is "**The Matrix Phases.**" The body attempts to maintain life as long as possible, but next the toxins might penetrate the cells themselves, and in these cellular phases, the cells are increasingly destroyed. The defense system is no longer able to excrete the toxins out of the cells, or out of the matrix by virtue of its own strength, and we name this inability, "**Regulation Rigidity.**" The **fifth and the sixth phases** in these **"Cellular Phases"** are "**The Degeneration Phase"** (with serious damage and destruction of large cell groups, their enzymatic functions, and energy production systems) that is much more difficult to influence, followed by the last, the **sixth phase** in this evolution scale of diseases, "**The Dedifferenation Phase,"** or **"The Neoplastic Phase."** Diseases of this phase are characterized by the development of undifferentiated, nonspecialized cell forms. Malignant diseases stand at the end of this phase. Each one of us should try to locate any animal presented on this six-phases table as part as our diagnostic effort, in order to be able to select the proper regime of anti-homotoxic drugs, to allow us to give a prognosis for each case, and to be able to evaluate our therapeutic success or failure.

Reckeweg noticed that a disease can start in one tissue (dermatitis in the skin), and later develops in another tissue (asthma in the lungs); this shift is called *vicariation*. Vicarius comes from Latin, *vicarious* = substitute. The disease might shift as well from one phase to another, and back and forth. **Progressive vicariation** is an aggravation of the total clinical signs, and **regressive vicariation** refers to an improvement of the clinical signs. We can evaluate our success or failure by locating our patient on this scale, and see if the clinical signs are improving or deteriorating. By using this scheme one can see that the development of dermatitis into asthma is considered to be a negative process, as the disease goes deeper into the animal to an impregnation phase. On the other hand, when we treat asthma, the occurrence of skin problems is a positive sign, and should not be suppressed. These temporary signs are expected, the owner should be notified in advance that these clinical signs are needed for the healing process. The healing process itself is going from vital organs towards body's parts of less importance, from the inside towards the outside, from the top to the bottom, and in reverse chronological order (ie, the clinical signs that appeared last, disappear first).

In view of what you have read so far, we might ask: What are the objectives of anti-homotoxic therapy?

- **Prevention of illness,** and that can be achieved by toxins avoidance (eg, a change in the environmental conditions, or change in the nutrition plan provided for the animal).
- **Symptoms management**, by reversion of symptoms (regressive vicariation) and supporting forces of spontaneous healing. When performing a symptomatic approach, a veterinarian can use the western diagnosis of his/her choice for the right remedy. The therapeutic indexes of homotoxicology books can easily help out an inexperienced veterinarian in making the choice of the proper remedy.
- **Detoxification** by induction of excretion and toxins elimination (through activation of excretory organs as liver, gallbladder, kidney, gastrointestinal system, lymphatic system, skin, respiratory system, and mucus membranes). Here we are going to use drainage remedies.**Regeneration of damaged tissue by organic function strengthening, cellular function activation, and immunomodulation,** by giving an animal organ preparation with enzymatic catalysts, and a properly selected nosode to clear up the animal out of toxins that might be present in deep tissues.

The therapeutic effort must aim to activate and support body's endogenous defense mechanisms, and that should be done without compounding the problems that are caused by toxins already present (antibiotics, hormones, etc.). For example, when we give 1,000 mg of acetylsalicylic acid (mol wt 180.2) ~ 5.5 nmol or 10^{20} molecules, means that each of 10^{14} animal cells are impacted by a million molecules of the active ingredient. Homotoxicology works with the weak stimuli that are characteristic of homeopathic therapy, as explained by Drs. Rudolf Arndt and Hugo Schultz: "The strongest stimuli by a given drug in a too-large-quantity (an overdose) will suspend life's functions, a strong stimuli might inhibit the bio-system, a moderately strong stimuli will accelerate life functions, but a weak stimuli will stimulate life functions."

There is another interesting aspect in homotoxicology named "**Immunological Bystander Reaction.**" When we give an animal a homeopathic remedy at the concentrations used in homotoxicology (there are minute quantities of ingredients in the remedy), it stimulates in situ macrophages to phagocytize the remedy. The ingredients are in amounts too small to produce a complete immunological reaction. After phagocytosis, the macrophages return molecules of the ingested substances to their surface. These molecules (motifs) are bound to membrane-related Major Histocompatibilty Complexes (MHCs) on the macrophages. Nearby naïve and undifferentiated lymphocytes (Th0) recognize the motifs, remove them from the macrophage, and bind them to their own receptors. This specific action is a signal for Th0 transformation to regulatory lymphocyte (Th3), a committed lymphocyte. The Th3 cells wander into regional lymph nodes, and via cell division multiply to many "motivated and committed" cell clones. Via blood vessels, these leave the lymph nodes and reach all organs and tissues. The indicated motifs facilitate an increased penetration of the Th3 cells into the relevant area. Chemotactic factors (complement factors, chemokines, etc.) from the inflamed area support this organo/histotrophy. As soon as Th3 reaches the target organ (recognition, similarity between their motifs and the target cells organ), Th3 cells immediately start to synthesize Transforming Growth Factor-beta (TGF-beta, the body's most potent anti-inflammatory cytokine) and start inducing Th2 to release interleukin- 4 and 10, which support the effect of TGF-beta. This stops inflammatory processes and regenerates normal tissue.

ANTI-HOMOTOXIC THERAPY OBJECTIVES

- **Prevention of illness**: Toxins avoidance
- **Symptom management**: Reversion of symptoms (regressive vicariation) supporting forces of spontaneous healing
- **Detoxification**: Excretion induction Homotoxins elimination
  - Excretory organs activation (LIV/GB, KID/BL, GI, Lymph, Skin/MM, Resp)
- **Regeneration**: Organic function strengthening, Cellular function activation, Immunomodulation
  - So, as far as therapeutic steps/stages one should work
- Stage 1: Symptomatic remedy
  - [avoid toxins and symptoms management: reversion of symptoms(regressive vicariation), supporting forces of spontaneous healing]
- Stage 2: **Drainage remedy**
  - [prevention of illness by detoxification: excretion and induction of homotoxins elimination, done by excretory organs activation (LIV/GB, KID/BL, GI, Lymph, Skin/MM, Resp)]
- Stage 3: **Organ preparation/catalyst/adj allopathic medic'**_[Regeneration: Organic function strengthening,
  - Cellular function activation]
- Stage 4: **Nosode/Injeel preparation**
  - [Immunomodulation]nAdd Rx at home + Ce + evaluation

Example: K-9 Seborrhea Stage 1: **Symptomatic remedy**_- Schwef-Heel
Stage 2: **Drainage remedy -_Galium**-Heel + Cutis compositum
Stage 3: **Organ preparation/ catalyst/adj allopathic medic** Ubichinon/Hormeel/Thyreoidea compositum
Stage 4: **Nosode/Injeel preparation** Immunomodulation] Psorinoheel nAdd Rx at home + Ce + evaluation

One can combine homotoxicology with acupuncture – homeosiniatry by using 5 elements:

Rx using Sheng Cycle	In Deficiency - Tonify the Parent In Excess - Sedate the Child
Rx using the Ko Cycle	In Deficiency - Sedate the Grandparent In Excess - Tonify the Grandparent
Rx using Sheng+Ko Cycles	In Deficiency - Tonify the Parent & Sedate the Grandparent In Excess - Sedate the Child & Tonify the Grandparent

Or use the 4 (8) Needles Technique for Deficiency:

(1) Tonify the Parent point of the affected ElementTonify the Horary point of the parent Element
(3) Sedate the Grandparent point of the affected Element
(4) Sedate the Horary point of the Grandparent Element

Or use the 4 (8) Needles Technique for Excess:

(1) Sedate the Child point of the affected Element
(2) Sedate the Horary point of the Son Element
(3) Tonify the Grandparent point of the affected Element
(4) Tonify the Horary point of the Grandparent Element

HOW TO PRESCRIBE ACCORDING TO SHENG OR KO CYCLES?

A **Tonification protocol** for of a specific process on one acupoint:

(1) Pin-point the deficient Process and select a specific remedy for it;
(2) Select a relevant tonification remedy;
(3) Mix the 2 remedies at the same syringe;
(4) Select the proper acupoint to be injected;
(5) Inject.

or -

A **Sedation protocol** for a specific process on one acupoint:

(1) Pin-point the Excessive Process and select a specific remedy for it;
(2) Select a relevant Sedative remedy;
(3) Mix the 2 remedies at the same syringe;
(4) Select the proper acupoint to be injected;
(5) Inject.

Needless to say, we can combine the two prescriptions to work on the Sheng + Ko Cycles

REGARDING THE ABOVE-MENTIONED PROTOCOLS WE SHOULD NOW ASK

(1) "What is a specific remedy for the Process at hand (pin-point the Process)?"

A specific remedy exists for every Zang Fu imbalance:

LU conditions	Euphorbium Comp ad us. vet.
LI conditions	Mucosa Comp
ST conditions	Nux vomica Homaccord
SP conditions	Momordica Comp
HT conditions	Cactus Comp
SI conditions	Veratrum Homaccord
BL conditions	Cantharis Comp
KID conditions	Berberis Homaccord
PC conditions	Apis Homaccord
TH conditions	Hormeel
GB conditions	Chelidonium Homaccord
LIV conditions	Hepar Comp Heel

(Note: This is the basic list, just "the tip of the iceberg"; more accurate and specific remedies can be found in the different veterinary guides provided by the different companies.)

(2) What remedies are used to Tonify or Sedate?

To Tonify in acute cases use	Coenzyme Comp
To Tonify in chronic cases use	Ubichinon Comp
To Sedate in acute cases use	Lymphomyosot
To Sedate in chronic cases use	Galium Heel

LET US WORK ON A CASE USING THE SHENG & KO CYCLES

Q: What is the TCVM diagnosis?

A: KID Chronic Deficiency

Therapeutic Plan: Tonify Metal pt. & Sedate Earth pt = Tonify KID-07, Sedate KID-03

Q: What is the specific remedy for the specific imbalanced process (KID)?

A: Berberis Homaccord

Q: Is it acute or chronic & what remedy accordingly to be given for tonification & sedation?

A: It is a chronic condition= Ubichinon for tonification, Galium Heel for sedation

Treatment Plan: Inject KID-07 with a mixture of Berberis Homaccord + Ubichinon and KID-03 with a mixture of Berberis Homaccord + Galium Heel

LET US WORK UP A CASE ACCORDING TO THE 4 (8) NEEDLES TECHNIQUE

4 Needles protocol for LIV Excess (chronic):

- Sedate LIV-02 (Fire pt of Wood Element) - Hepar Comp Heel
- Sedate HT-08 (Fire pt of Fire Element) - Galium Heel
- Tonify LIV-04 (Metal pt of Wood Element) - Hepar Comp HeelTonify LU-08 (Metal pt of Metal Element) - Ubichinon Comp

4 Needles protocol for SP Deficiency (chronic):

- Tonify SP-02 (Fire pt of Earth Element) - Momordica Comp
- Tonify HT-08 (Fire pt of Fire Element) - Ubichinon Comp
- Sedate SP-01 (Wood pt of Earth Element) - Momordica Comp
- Sedate LIV-01 (Wood pt of Wood Element) - Galium Heel

TCM APPROACH TO CANCER — PART 1

Constance A. DiNatale, DVM
Veterinary Acupuncture and Complementary Therapy
Winter Park, FL

Traditional Chinese Veterinary Medicine (TCVM) uses five branches to treat disease: diet, herbs, acupuncture, tui-na, and qi kung. We can use all of these treatment strategies to help see patients with cancer live the best quality life possible.

Before going into the different methods used to treat cancer, it is important to mention the Shen, or mind, of our patients and their caretakers. In Chinese Medicine, the Shen encompasses the spirit and the mind. An animal with bright eyes and a happy countenance has good Shen. Shen is directly affected by the state of the Heart. In TCVM, the Heart refers to an organ system. The emotion associated with Heart is joy, and when there is a lack of joy, the Shen is depressed and the eyes lose their brightness.

Animals with cancer do not understand they have a disease. They know they don't feel good, and they know their owner is distressed and doesn't feel joy when they see them. We can encourage healing of the Shen of both patients and caretakers by reminding people to continue living. Allow the animal to continue working and performing as permissible. Go on walks and picnics and have fun. Don't allow friends and family to come over and mourn the living animal. Show people massage, acupressure, and other physical modalities to allow them to participate in the healing process. It is OK to be sad, but not OK to cease living while we are still alive.

If the Shen disturbance seems to be strictly Heart related (weak HT pulse, dreams, restless at night), Tian Wan Bu Xin Wan can be given. For depression caused by Liver Qi stagnation (purple tongue, isolation), think of Xiao Yao San or Cyperus 18 (Institute for Traditional Medicine).

Norman Cousins said the greatest tragedy of life is not death, but what dies in us while we live.

The Chinese recognize many different causes of cancer:

- Cancer arises from toxic sources, such as radiation, environmental toxins, or even some vaccinations.
- Cancer can be caused from emotional changes leading to Qi stagnation, demonstrated often in conventional medical literature, as in the case of breast cancer.
- Old injuries can lead to Blood Stasis, as seen in cases of osteosarcoma that had panosteitis of the same limb when young.
- Diet can play a role, whereby poor eating habits or poor diet choices leads to food stagnation, phlegm accumulation, and finally cancer.
- Zang-fu disharmony leads to organ deficiency, and stagnation.

One can often differentiate these patterns based on history or clinical presentation. Bone cancer can sometimes be found in animals with a history of panosteitis or trauma. A recent report found a link between bladder cancer in dogs and obesity (diet leading to phlegm accumulation), living in marshy areas with agricultural run-off (toxin invasion), and receiving monthly topical flea prevention (toxin invasion). It is also common to see various cancers in animals that have a long history of inflammatory bowel disease, vomiting, "sensitive stomachs," and suppressed skin disease (Zang-fu disharmony, leading to deficiency and stagnation).

In all of our cancer therapies, we want to get things moving. Cancer is always about a stagnation of Qi and/or Blood, where things have ground to a halt and now the body has lost control. The key point that is often forgotten is that many cancers started as a deficiency, a weakness that allowed friction and inflammation and deregulation to occur. We allopathically attack cancers with an herbal and nutriceutical arsenal meant to attack, destroy, crush, crack, and purge the tumor. This sounds like, and is, herbal chemotherapy.

Herbal chemo does have its place. When we look at aggressive, "hot" cancers that are metabolically active in a vital, strong animal, we may use powerful products and try beating the cancer cells into submission. Yet even the hottest, most excess animal will quickly deplete its essence while battling cancer, so please remember to always nurture your cancer animals with thoughtful, nourishing foods, herbs and acupuncture.

When a patient with cancer is examined, there are a wide variety of pulses ranging from slippery, choppy, wiry, full to weak, deep and thin. Tongues range from swollen, pale, wet blobs to thin, dark, red or purple strips.

Patients with osteosarcoma, hemangiosarcoma, and bladder cancer often present with excess heat and stagnation. Tongues are dark red, purple, or both, and pulses are full, bounding, choppy, and/or slippery, even postoperatively.

Some animals have patterns that appear excess and deficient; they may pant a lot or display polyuria/polydipsia (PU/PD). The tongue is usually some degree of lavender to purple, and the coating is dull. There is usually a history of low-grade chronic disease. Pulses can be fast, thready, thin and tight, often with blood deficiency as well as stagnation. The hair coat is often dull, and the nails are full, thickened, ridged or discolored. The focus is on moving and tonifying blood.

ACUPUNCTURE

Acupuncture can be an incredible tool for working with cancer. Our only contraindication is not to directly needle around a tumor. Because needles increase Qi to an area, they can accelerate tumor growth in some cases, when used locally.

Uses for acupuncture include moving Blood and Qi stasis, tonifying Qi, Yin, and Blood, transforming Phlegm and draining Damp, and clearing Heat.

Points used to activate Blood and dispense Stagnation could be SP 10, SP 6, ST 36, LV 3, BL 18, LV 2, BL 60, SP 8, LI 11, and PC 5. These points can be used whenever a solid mass is present, representing Blood Stagnation.

In an animal with concurrent weakness, focus is on ST 36, SP 6, and SP 10, as these points are also tonifying.

For an animal with concurrent heat signs, one can choose LV 2, LI 11, or BL 18.

If excess heat is present, use LI 4, LI 11m GV 14, wei jian, er jian, ST 44, LV 2, BL 17, CV 12, ST 36, ST 40, TH 5.

Choose heat-draining points to draw heat from the affected channel or system. Wei jian would be good for anal gland carcinoma, ST 44 for mouth cancer, and LI 4 for face cancer.

Acupuncture for tonification could include KI 3, SP 6, BL 23 and KI 7 for Yin and SP 6, BL 20 BL 17, LV 8, PC 6, HT 7 and SP 10 for supplementing Blood.

Use ST 36, BL 20, LI 4 and CV 4 to boost Qi.

To transform Phlegm and drain Damp, we can use ST 40, SP 9, CV 12, PC 6, SP 6 and CV 17.

Acupuncture has the most widespread reputation for helping patients with chemotherapy side effects.

- For gastrointestinal upset, we use CV 12, ST 36, or PC 6 for nausea and vomiting
- To stimulate appetite, use Shan gen
- For diarrhea, use ST 36, ST 25, BL 25, BL 28 or GV 1
- For leukopenia, inject B12 into BL 17 and needle SP 10, LI 4, LI 11, GV 14 and ST 36
- For Shen disturbance, remember to use An Shen, HT 7, BL 15 and BL 44

For animals getting chemotherapy, try to acupuncture a few days before or after chemo treatments to keep the Qi flowing and to minimize side effects.

TCM APPROACH TO CANCER — PART 2

Veterinary Acupuncture and Complementary Therapy
Winter Park, FL

HERBAL THERAPIES

Use whatever knowledge is available to determine the presenting pattern. If the animal presents with polyuria/polydipsia (PU/PD) and other heat signs, determine if the cause is excess, deficiency, or drug-induced. The age of an animal is helpful in determining the strength of a formula, though some 12-year-old dogs have better Qi and Shen than a chronically ill, Jing-deficient 2-year-old dog. The former could take a stronger formula.

It is also very important to address underlying Spleen Qi deficiency or Dampness when choosing a formula. A weak Spleen cannot assimilate a strong Qi/Blood moving formula, and cannot handle a Blood tonifying formula. Spleen problems should be addressed as a priority over most other problems when treating herbally and with food therapy.

Many companions offer herbal formulas to treat cancers. If the primary function of the formula lists Blood moving or cracking, Qi moving, and Heat or Toxin clearing as the main function(s), it is probably a very powerful formula to be reserved for animals with strong constitutions. Formulas which also add herbs to tonify Blood or Qi, depending on the percentage included, may be safer for older or sicker animals. It is helpful to have some knowledge of the types of herbs used in cancer formulas so one can identify which formulas contain harsher herbs, and thus can cause more side effects. An animal with mast cell cancer or hemangiosarcoma may present with Blood deficiency in the face of Blood stagnation. Using a strong Blood mover in these deficient animals, without addressing underlying Blood or Spleen deficiencies, can cause some formulas to act like chemo and depress the bone marrow. One can also get gastrointestinal distress and lethargy.

Some animals with significant Qi deficiency can do quite well on astragalus-based formulas that tonify and also move Qi to some degree. Some will remain on these herbs alone, while others can start to add stronger formulas as their energy and vitality improve.

Use formulas specific for concurrent diseases. Most cancer animals have a history that brought them to this point, whether it was chronic urinary tract infections, chronic inflammation, inflammatory bowel disease, or dermatological disorders. These chronic patterns must be addressed, sometimes sooner, sometimes later, depending on the severity of the signs. Great improvements can often be seen in a case by adding a nourishing Yin tonic or a Liver-Gallbladder heat-draining formula.

HERBAL FORMULAS

The following are a small sampling of formulas that can be useful in treating cancers.

For Excess, Damp Heat type cancers:
- Stasis Breaker (Jing Tang Herbals)
- Chih-ko and Curcuma (ITM)

For older, weaker animals with aggressive cancer:
- Max's Formula (Jing Tang Herbals)
- Chih-ko and Curcuma (ITM)

The following are formulas for specific cancers (use with a general formula).

Brain Cancer:
- Otolith (ITM)
- Stasis in the Mansion of the Mind (Jing Tang Herbals)

Liver Cancer:
- Sparghanium (ITM) – can be used alone for geriatrics

Bladder Cancer:
- Shao Fu Zhu Yu Tang
- Long Dan Xie Gan Wan

Mast Cell Cancer:
- Xue Fu Zhu Yu Tang (patent – many sources)

Lung Cancer:
- Belamcanda (ITM) – excess pattern

Thyroid Cancer:
- Nei Xiao Luo Li Wan

Support Formulas:
- Astragalus 10+ (ITM)
- Wei Qi Booster (Jing Tang Herbals)
  - Many companies have formulas like those above that support immune function by tonifying Wei Qi, and many have Qi and Blood tonics as well. The polysaccharides in astragalus-containing formulas, as well as mushroom-based formulas, support bone marrow integrity while undergoing chemotherapy.
- Chemo Blood Support Formula (Golden Flower) – anemia, leukopenia
- Milletia 10 (ITM) – anemia, leuKopenia
- Antler 8 (ITM) – anemia
- Liu Wei Di Huang, Zhi Bai Di Huang Wan (patents) – Kidney Yin deficiency
- Tang Kuei 18 (ITM) – useful in cancer animals with concurrent Blood deficiency such as many brain cancers, some hemangiosarcomas and mast cell cases
- Ban Xia Xie Xin Tang (many sources) – gastrointestinal damp heat from chemo

DIET AND CANCER

Our final consideration is diet. There are many theories on how humans with cancer should be fed, although most veterinarians refer to the work of Greg Ogilvie, DVM, for current research findings.

Dr. Ogilvie has done extensive research on dogs with lymphosarcoma and osteosarcoma and the changes these cancers produce metabolically. Dr. Ogilvie found that dogs with these cancers had higher urinary nitrogen output, decreased protein synthesis, and increased glucose flux. Insulin resistance is common, causing adipocytes to dump fat from the body, leading to weight loss and cachexia. Carbohydrates are used preferentially by tumors and are converted to lactic acid. This lactic acid must be turned back into glucose by the liver at great expense to the body. The lactic acid also contributes, along with other cancer byproducts, to the nausea our patients feel.

The anorexia we often see can be benefited by using a wide variety of foods to prevent the animal from associating specific foods with the nausea. Meals should be small and fed at room temperature. Meals should not be repeated, despite a good appetite, lest the animal overindulge and never eat the food again.

The trend towards high protein, very low carbohydrate diets can be beneficial to some, but does not seem to be a universally advantageous diet. Carbohydrates that can and should be fed are complex, high in fiber, and of relatively low glycemic index. Grains should be soaked overnight and then cooked “low and slow” to get maximum assimilation. Whole oats, barley, quinoa, and millet have a low glycemic index and are very nutritious. Rice has a higher glycemic index and may be less desirable. Sweet potatoes have a relatively high glycemic index but are such a nutritionally valuable food, with a high fiber content and fructo-oligosaccharide content that one should feel fine feeding them. Other roots are also good nutritional choices except white potato, whose high sugar content may not be such a good bet.

All vegetables should be cooked. Animals lack the enzymes which digest the hemicellulose in plant cell walls, thereby limiting the nutritional value of the food.

Diets should be based predominantly on foods with “neutral” energetics (neither excessively hot nor cold), with smaller amounts of hotter or cooler foods added to aid the prevalent pattern. Charts and books are readily available to determine the thermal and energetic properties of different foods. In general, one can use 35% to 60% protein, 20% to 30% grains and/or roots, and 10% to 20% vegetables. Supplements should be added to balance the calcium/phosphorus ratio and to provide iodine, trace minerals, antioxidants, and essential fatty acids.

For an animal with heat signs, such as a dog with osteosarcoma with rapid, full pulses and a dark tongue, one could feed turkey as the primary protein, and add or substitute white fish to cool the diet more. Barley would drain damp heat while tonifying Spleen, and green beans would tonify Yin and Spleen. Some sweet potato could be added in small amounts to tonify Spleen and Blood if needed, or one could use yucca for its wonderful Yin-tonifying (anti-inflammatory) properties.

An animal with mast cell tumors is often Blood deficient. Animals with Blood-deficient cancers would benefit from more beef, liver a few times a week, hard-boiled eggs, or oily fish like sardines or salmon. Grains and starches could be oats or yams. Vegetables would be beets, broccoli, and dark, leafy greens. Fruits could be raisins, purple grapes, dates, or figs.

A RENAISSANCE – THE TRADITION AND SCIENCE BEHIND THE USE OF HERBS IN VETERINARY MEDICINE

Barbara Fougere, BSc, BVMS (Hons), BHSc (Comp Med), MODT, MHSc (Herb Med), CVA, CVCP, CVBM
College of Integrative Veterinary Therapies
All Natural Vet Care, Sydney, Australia

WESTERN VETERINARY HERBAL MEDICINE

Contemporary veterinary herbal medicine is both a science and a tradition. It represents the synthesis of many fields including botany, pharmacology, pharmacognosy, philosophy, history, pathology, ethnoveterinary medicine, research, clinical practice, and monograph study. In the last 50 years or so, science has provided new perspectives on the how herbs work, and several herbs have made their way into mainstream medicine, particularly in Europe. Randomized clinical trials of single herb interventions are relatively easy to undertake, and certainly in human medicine increasing numbers of studies are being published. Herbs may represent simply substitutes for drugs and these single herb studies support this approach.

Herbal medicine is more than this though. Undertaking herbal medicine as a discipline requires changing the way we think about medicine; from using drugs or herbs to relieve symptoms from a pharmacological perspective, towards using herbs to fundamentally alter the physiology of our patients towards health. Herbal medicine is thus aimed at restoring homeostasis by targeting predisposing and perpetuating causes of disease through lifestyle changes, nutrition, and individually prescribed herbal formulas (typically up to six herbs). A veterinary consultation can take 30 minutes to an hour. Thus the approach is complex and also a weakness when seeking to enhance the evidence base for its efficacy. Another problem with researching herbal medicine is that the medicine itself doesn't exert its physiological action through a single mechanism, as do many drugs. Instead the action of any herb or combination depends on complex interactions and activity of thousands of phytochemicals contained therein. This is in fact one of the key strengths of herbal medicine.

The complexity and multiple constituents found in plant tissues means that identification of active components is relatively recent (depending on advances in laboratory techniques) and is far from complete. The traditional interventions of herbal medicine have relied on crude extracts of plants from teas, decoctions, dried herbs and tinctures. There is a considerable body of science that exists on the physiological effects of isolated constituents and most of these are from animal studies. When we consider the plethora of research available from these studies, it might be true to say that more is known about herbal actions and pharmacology in "pocket pets" (mice, rats and guinea pigs—also referred to as laboratory animals) than any other domestic species. Knowing some of the key constituents in a herb and their actions, along with knowledge of its traditional use provides a basis upon which to prescribe in veterinary medicine.

So with all these limitations, why use an herb when we have well researched, established medicines for many veterinary conditions? It is important to keep in mind that where a conventional medicine is both safe and effective, it makes sense to use it. However, for many conditions, drug use isn't safe and not always effective; chronic diseases are chronic because the medicine is not restoring health (albeit relieving symptoms). And while we currently have good treatment options for patients with infections or parasite burdens, for example, we are challenged by diseases like cancer and allergic and degenerative diseases in animals. As well the rising issues of multiple drug resistance, drug residues and an increasing emergence of organic livestock production, mean that for all these reasons, the traditions of herbal medicine deserve consideration.

A LONG TRADITION OF HERBAL USE IN VETERINARY MEDICINE

The use of herbal treatments within veterinary medicine is not a new phenomenon, nor has it always been considered alternative! Ever since veterinary medicine as a discipline began in Europe in the 17th and ....18th centuries, plants have been an important part of veterinary herbal medicine. In fact many herbs were considered orthodox within the veterinary profession. These include herbs such as ginger, aloe, peppermint, cascara, senna, betel nut, calabar, catechu, kamala, fern, and others that are featured in the veterinary pharmacology texts and veterinary medical texts into the 1960s .

An interesting insight into veterinary medicine of the mid 1850s can be found in Dr. Finlay Dunn of Edinburgh Veterinary College's book *Veterinary Medicines: Their Actions and Uses.* Our veterinary forefathers (for there were no foremothers) were scientists. Perhaps they were not familiar with double-blind placebo-controlled protocols, but they were intelligent and curious and adept at experimentation, often to the detriment of their patients! From this book a summary of the plant medicines appears below (Table 1). They were well defined—the species, properties, and preparation—and much was known about their poisonous effects. Many experiments are discussed in the text, along with well observed species differences in doses and tolerances as well as poison susceptibility. For example, hemlock, a well-known poison, was well tolerated in horses, sheep, and cattle but easily caused death in dogs and cats (as experiments proved!). Herbs were rarely applied singularly, but in combinations with other herbs that augmented their toxicity or enhanced their efficacy. Contraindications were also stated.

Table 1. Summary of Medicinal Plants Outlined in Finlay Dunn's *Veterinary Medicines: Their Actions and Uses* (from the mid 1850s)

Herb	Action & Uses	Species
Aconite (*Aconitum napellus*)*	Powerful general sedative, anodyne, antispasmodic. Pneumonia, pleurisy, bronchitis. pain	Horses, cattle, dogs
Aloes (various species)	Cathartic, tonic, purgative, vermifuge. Constipation, colic, foreign bodies, febrile attacks.	Horse, cattle, sheep, swine, dogs
Anise (*Pimpinella anisum*)	Stomachic, carminative, flavoring, use with purgatives	Horse, cattle, sheep, swine, dogs
Assasoetida (*Narthex assafoetida*)	Stimulant, carminative, vermifuge, chronic coughs, chorea	Horses, cattle, dogs
Balsams of Tulu and Peru	Mildly tonic, stimulant, expectorant, vulnerary	
Belladonna (*Atropa belladonna*)*	Anodyne, antispasmodic, pupil dilation, narcotic, calmative. Tetanus, cancer pain, cystitis, performing operations on the eye	Horses, cattle, dogs.
Buckthorn (*Rhamus catharticus*)	Mildly cathartic. Distemper	Dogs, cats
Camphor (*Camphora officinalis*)*	Sedative, calmative, antispasmodic, slightly stimulant. Nervous irritability, pulmonary disease.	Horses, cattle, dogs
Caraway (*Corium carui*)	Stomachic , carminative, flavoring	
Cardamom (*Electtaria cardamomum*)	Mildly stimulant, stomachic, carminative, flavoring.	
Castor oil (*Ricinus communis*)*	Purgative, cathartic. Dysentery, enteritis, peritonitis, hernia, kidney and bladder disease	Dog, pig
Catechu (*Acacia catechu*)	Astringent, antiseptic (tannins) General atony, excess mucous discharges, flatulence. Externally	Horse, cattle, sheep, swine, dogs
Chamomile (*Anthemis nobilis*)	Stomachic, carminative (oil) mildly stimulant, tonic (tannins). Indigestion. External vulnerary	
Chinchona	Astringent, antiseptic, tonic, antiperiodic. Improves appetite, digestion, chronic diarrhea, convalescence, diabetes	Cattle, dogs, sheep, horses
Colchicum (*Colchicum autumnale*)	Cathartic, diuretic, emetic, sedative Rheumatism, ophthalmia	Horses, cattle, dogs
Croton seeds and oil (*Croton tiglium*)	Cathartic and externally counter irritant. Tetanus, constipation, congestive puerperal fever, arthritis	Horse, cattle, sheep, dogs
Digitalis (*Digitalis purpurea*)*	Topical irritant, sedative, diuretic	Horses, cattle, dogs
Euphorbium – cactus	Topical irritant	Horses, dogs, cattle
Fennel (*Foeniculum officinale*)	Stomachic, carminative, flavoring	
Gentian (*Gentiana lutea*)	Bitter, stomachic, tonic. Chronic complaints, convalescence, simple indigestion, vermifuge, jaundice	Horse, cattle, sheep, dogs
Ginger (*Zingiber officinale*)	Slightly irritant, stomachic, carminative, mildly tonic. Stimulates mucous secretions, facilitates digestion, prevents flatus. Adjunct to purgatives	Horse, cattle, sheep, dogs
Hellebore (*Helleborus niger*)*	Purgative, anthelmintic, emetic	
Hemlock (*Conium maculatum*)*	Narcotic in small animals, carmitive rheumatism, neuralgia, diuretic, externally anodyne	Horses, cattle
Henbane (*Hyoscyamus niger*)*	Anodyne, calmative, antispasmodic. Little effect on ruminants. Dilation of pupils, substitute for opium in dogs.	Dogs.

Table continues on following page

Ipecacuan (*Cephaelis ipecacuanha*)	Irritant, emetic, slightly cathartic, sedative. Little effect on horses or cattle. Emetic in dogs, laxative. Arrest febrile complaints, eye, brain, lungs.	Cats and dogs.
Jalap (*Exogonium purga*)	Irritant, cathartic. Purgative for dog and vermifuge	Dogs
Juniper (*Juniperus communis*)	Carminative, diuretic, stomachic. Prevent sheep rot. Powerful diuretic. Oil is used for skin disease.	Horse, cattle, sheep, dogs
Linseed (*Linium* sp). Flax	Oil- cathartic, emollient. Laxative, relieving irritant poisoning, colic, relieving choking, rectal and bladder soothing	Horse, cattle, sheep, dogs
Licorice root (*Glycyrrhiza glabra*)	Demulcent, emollient, flavoring	
Marshmallow (*Althea officinalis*)	Demulcent, emollient	
Mustard (*Sinapis nigra*)	Stomachic, carminative, external counter irritant. Bronchitis, pleurisy, arthritis, wounds	Horse, cattle, dogs
Myrrh	Stimulating tonic on digestion. Indigestion, mucous discharges. Externally for indolent sores and ulcerations	Horse, cattle, dogs
Nux vomica (*Stychos nux vomica*)*	Nervous stimulant esp spinal cord. Chronic paralysis, chorea, stringhalt	Horse, cattle, dogs
Oak bark (*Quercus robur*)	Astringent, tonic. Diarrhoea, dysentery. Arresting gangrene, ulcers. Uterine prolapse, rectal prolapse.	Horse, cattle, sheep, dogs
Olive oil	Laxative, emollient	
Opium (*Papaver somnifera*)	Narcotic, sedative, anodyne, stimulant, antispasmodic, diaphoretic, febrifuge, impuissant of mucous discharges. Source of morphine, codeine, narcoline, etc. Bronchitis, pneumonia, pleurisy, influenzas, asthma, diarrhea, colic, chronic vomiting, peritonitis, enteritis, tetanus, rheumatism	Horse, cattle, sheep, dogs
Peppermint (*Mentha piperita*)	Stomachic, carminative, antispasmodic, flavoring. Indigestion, flatus, griping.	Horse, cattle, dogs
Peppers (sp)	Irritant, stomachic, rubefacient. Simple indigestion, colic. External use	Horse, cattle, sheep, dogs, swine
Rhubarb (*Rheum palmatum*) sp.	Tonic, astringent, cathartic. Astringent on skin. Facilitates digestion, cathartic. Diarrhea, dysentery. Laxative.	Horse, cattle , sheep, dogs, cats
Savin (tops of *Juniperus sabina*)*	Anthelmintic	Horses, dogs
Sugar (*Saccharum officinarum*)	Demulcent, emollient, nutritive, antiseptic, laxative. Removing spots on cornea, sores.	Horse, cattle , sheep , dogs
Tobacco (*Nicotiana tabacum*)	Sedative, antispasmodic, anthelmintic, auxiliary emetic, cathartic. Colic, tympanitis, hernia (smoke clyster). Enteritis, peritonitis. Ascaridicide. Externally mange in dogs, fleas, ticks, but can be fatal as absorbed thru the skin.	
Turpentines (incl frankincense)*	Topical irritants, stimulants in indigestion, colic, general debility, laxative, anthelmintic, diuretic. Oil is used colic	Horses, cattle, dogs.
Valerian (*Valeriana officinalis*)	Antispasmodic, calmative, anthelmintic, diffusible stimulant. Acts little on horses and cattle. Epilepsy in dogs, chorea. Allyas nervous irritability	Dogs, cats
Veratum (*Veratum album*)*	Emetic, purgative, anthelmintic. Applied externally for skin parasites	Horse, cattle, dogs

* Very low safety margin.

Other medicines described in the text include: Acetic acid, alcohol, alum, ammonia, antimony, arsenic, axunge (hog's lard), calcium salts, cantharide, charcoal, chlorine, chloroform, cod liver oil, copper compounds, creosote, ergot, ether, galls (oak), gelatine, gum Arabic, honey, iodine, iron compounds, lead compounds, magnesium compounds, mercury compounds, hydrochloric acid, naptha, nitric acid, petroleum, potassium compounds, prussic acid, pyroxilic spirit, soap, silver compounds, sodium compounds, spermaceti, starch, sulfur, sulfuric acid, spirit nitre, water, wax and zinc compounds. This list and the above table represent the sum total of veterinary medicines taught at the Edinburgh Veterinary College in 1854.

Why did we stop using herbs in veterinary medicine? In the late 19th century the American Medical Association faced vigorous competition from several quarters including naturopathic medicine, eclectic medicine, physiomedicalism, herbal medicine, and homeopathic medicine. All these were also employed by veterinarians of the day. There were some 4000 medical schools offering medical degrees after as little as 2 year's study. The AMA sought to reform medical education in a strong political move, deeming any approach other than allopathic based on the sciences of the day essentially quackery. Under the AMA's Council on Medical Education they commissioned a lengthy study of medical education called the Flexner Report which was published in 1910. The Report strongly influenced both medical and veterinary education resulting in the elimination of poorer, two-year schools of both disciplines with many of the schools offering anything but allopathic medicine forced to close down. Education was standardized and strongly regulated by the AMA. Since the discovery and use of sulfa drugs, antibiotics such as penicillin, and synthetic drugs, there has been a dramatic decline in the popularity of medicinal plant use in therapy. In parallel, within a decade or two the study of herbs all but disappeared from the curriculum of Western veterinary schools. Instead, medical plants were replaced with the toxicology of weeds. Now, the pendulum has swung to the other extreme: a resurgence of interest in the study and use of medicinal plants has been taking place during the last two decades.

HERBAL MEDICINE IS STILL THE MOST WIDELY USED VETERINARY MEDICINE

Meanwhile the rest of the planet has still largely depended upon plant based medicines for animal health care for many obvious reasons. In most African countries for example, these include manpower and logistical inputs; Scarce and erratic supply of veterinary drugs and supplies; High cost of veterinary drugs and supplies; Poor communication facilities and other modern amenities; Counter-productive government policies, which do not promote the complementary utilization of orthodox and indigenous knowledge systems ; Inadequate attention to the development of ethnoveterinary medicine and other indigenous knowledge systems. In countries like India, one survey shows that about 75% of the farmers use traditional veterinary methods. The main reasons stated for turning to traditional treatment are 1) no side effects, 2) low cost, and 3) lack of modern veterinary facilities. Foot-and-mouth disease, mastitis, fever, bloat, diarrhoea and helminthiasis are the diseases most commonly treated by means of ethnoveterinary medicine in cattle, sheep and goats, the mainstay of agriculture. The main plants used in one survey were pepper, ginger, turmeric, garlic, (*Allium sativum*), and preparations made from neem (*Azadirachta indica*) and tamarind (*Tamarindus indicus*). These sort of surveys and findings offer us new approaches, new ways of using familiar plants and perhaps some solutions to the issues we face in modern Western veterinary medicine.

Traditional veterinary practices are no longer considered as inferior, unlikely to work, or backward. Currently research into ethnoveterinary practices is intense. The whole field of ethnoveterinary medicine in livestock development is considered a mine of potentially useful information for sustainable animal health management systems that can benefit the rest of the world and there is a plethora of published literature 6 on the plants that are being used successfully for infections, parasites and many other conditions. Medicinal plants are commonly available in abundance. They not only offer the local population access to safe and effective medicines for human and animal health, they are valuable for modern medicine as sources of direct therapeutic agents; as raw materials for more complex semi-synthetic chemical compounds; as models for new synthetic compounds; and finally as taxonomic markers for the discovery of new compounds. Traditional herbal medicines are not only our past but sources of future medicines!

RENAISSANCE – THE SCIENCE AND ART OF HERBAL MEDIICNE

The literature is still relatively sparse in regards to veterinary applications of herbal medicine so there is a need to consider the herbal tradition as well as human phytomedicine and science for answers. The Veterinary Botanical Medicine Association is a group of veterinarians and herbalists dedicated to developing responsible herbal practice by encouraging research, education, strengthening industry relations (the source of our "new" medicines), keeping herbal tradition alive as a valid information source, having an influence in regulatory affairs and increasing professional acceptance of herbal medicine for animals.

The central issues in veterinary herbal medicine today are safety and efficacy. The whole field of herbal medicine in the modern veterinary setting is still experimental at best. While safety of many herbs has been demonstrated (through traditional use and science) in people and laboratory animals, safety of most medicinal herbs in domestic animals is still largely unknown, though, based on experience surprisingly few adverse events have been observed. As in human herbal medicine the safety, potency, and quality of herbal products and therefore the regulation and the registration of herbal products is a daunting issue. As practitioners, we need to consider the scientific rationale for the selection (if there is one), our clinical experience, and also draw on traditional knowledge.

Following are a just a few research summaries that support the use of herbs in veterinary practice.

Ginkgo

In Germany an open clinical trial was conducted in 10 veterinary practices. Ginkgo leaf extract was administered to 42 elderly dogs (average 11.4 years) at a daily dose of 40 mg/ 10 kg body weight for 8 weeks. Geriatric behavioral disturbances (mean duration 12 months) were significantly reduced after 8 weeks of treatment; 36% of the dogs were completely free of clinical signs at the end of the study and efficacy was judged as good or very good in 79% of the dogs. The study suggested that Ginkgo leaf extract appears to be an efficacious agent that provides a safe dietary supplement for the elderly dog with age-related behavioral disturbances

Panax Ginseng

A randomized controlled clinical trial on the efficacy of ginseng on geriatric dogs was reported in Boston in 2006. This Finish study on 80 geriatric dogs were randomsied to be given 40mg of Ginseng extract plus brewers yeast and the controls were given brewers yeast alone. The ginseng dose varied between 1.7 and 4.4 mg/kg /day depending on the size of the dog. From the start of the trial to 4 weeks, changes in 6 of 7 mental outcome measures between the treatment group and the control were significantly different. And at the end of the 8 weeks both mental and physical outcomes had improved more in the Ginseng group. Deterioration in both groups was seen after treatment ended. Ginseng was shown to improve the overall wellbeing of the geriatric dogs.

Milk Thistle

In two older trials, dogs were poisoned with hepatotoxic mushroom extract and treated with silymarin or silibinin. Treatment improved liver tissue and also survival rates. In the first trial, compared with prednsiolone, cytochrome C, and penicillin, dogs receiving Milk Thistle had liver enzymes that remained nearly normal throughout the testing period, whereas those of control dogs increased dramatically. In the second trial none of the dogs treated with silibin died whereas 4 of 12 dogs in the control group died.

Echinacea

In 2003 an open multi-centered veterinary clinical trial, Echinacea was administered to 41 dogs with manifestations of chronic and seasonal upper respiratory tract infections, including pharyngitis/tonsillitis, bronchitis, and kennel cough. Each dog was at an individual stage of the disease, with various symptoms and different severity scores, at start of treatment. There was no control group. Echinacea powder (1:3) was administered with food at a dose of 1.0 g/10 kg body weight once daily for 8 weeks. Overall efficacy showed significant improvement for 92% of 39 dogs after 4 weeks of treatment and this was confirmed after 8 weeks. Efficacy was not proven in the study (since there was no control group); however, it suggested that Echinacea can be recommended as a well-tolerated alternative treatment of canine upper respiratory tract infections.

CONCLUSION

The renaissance of veterinary herbal medicine is upon us. We reach back into tradition and search for clues and we take hold of science to provide the best of both medicines. Ultimately, as veterinarians, our pharmacopeia is greatly expanded and our limitations are reduced.

WESTERN HERBAL REMEDIES – MODES OF ACTION AND EFFICACY

Medicinal plants form the basis of healthcare for more than 80% of the world's current population, and their animals! For the rest of the planet, plants are critical to pharmaceutical research and drug development, with many plant constituents providing the basis of many of our drugs. It is estimated that 25% of prescriptions written in the US contain plant-derived active ingredients and 50% of fungal products are included. An even larger percent are based on semi-synthetic or wholly synthetic ingredients originally isolated from plants

Plant medicines are different from drugs, however. A single plant can contain thousands of different bioactive phytocompounds, and when herbal medicines are combined into formulas, the final medicine can have even more. This complexity is one of the most challenging aspects of herbal medicine research today.

The use of medicinal herbs and bioactive phytochemicals and our scientific knowledge of them comprises the modern field of phytosciences. This relatively new science involves the fields of medicine, biochemistry, physiology, chemistry, toxicology, agriculture and other diverse areas. Much of the contemporary research in herbs is about trying to determine whether traditional herb uses are actually supported, and by what mechanism. While there is ample scientific evidence on many isolated phytochemicals (mainly animal studies) and their physiological effects, we still do not understand the complete activity of most herbs, nor their effects when in combination. There are also other components in medicinal herbs such as minerals, sugars, vitamins, amino acids, lipids and other pharmacologically considered "lesser important" constituents, that can support health and healing.

An important resource is Dr. Duke's Phytochemical and Ethnobotanical Database, www.ars-grin.gov/duke, which can be accessed to find out what nutritional and other constituents occur within any given herb and which herbs contain a particular constituent. Several of the most common constituent categories with research that supports their traditional and modern use include the following.

Flavonoids are found in many plants and in high levels in Hawthorn, Grapes, Elderflower and Bilberry. Flavonoids and Proanthocyanidins (which are oligomers of flavonoids.) are almost universally antioxidant, most are anti-inflammatory and anti-neoplastic, anti-allergic and they reduce capillary permeability and fragility.

Anthraquinones are red or yellow pigments found in well-known laxative herbs including *aloe vera*, senna, yellow dock, turkey rhubarb and cascara. Their laxative effects have been supported by pharmacological research and they also have anti-inflammatory action.

Coumarins are found in many plants including Lavender, Horse chestnut, Dandelion, solanaceous plants, Poppies and Sweet Clover, Parsley and Angelica. Its fermentation product dicoumarol is a potent anti-clotting agent and forms the basis of warfarin. Coumarin actions include antibacterial, spasmolytic, vasodilative and antiedema. As medical herbs, they have use as venous and lymphatic vessel tonics.

Alkaloids are derived from amino acids and tend to be bitter tasting (thus acting on the digestive system). They are precipitated by tannins, so should not be mixed together (tannins can therefore be used to treat acute alkaloid toxicity). Pyrrolizidine alkaloids as a subgroup, are important for their potential toxicity for example in Comfrey. Another group, *isoquinolone* alkaloids include berberine, hydrastine and sanguinarine found in herbs such as Barberry, Oregon Grape root, Goldenseal and Blood Root). These alkaloids have actions that include antimicrobial, antioxidant, anti-inflammatory, ionotropic and antineoplastic.

Saponins generally have a sweet taste and lather in water. They are found in herbs such as Wild yam, Panax ginseng, Astragalus, Licorice and Ivy. They tend to have steroidal molecules with the ability to modulate effects on steroidal receptors. They have demonstrated anti-inflammatory and antiviral effects. They increase mucous production in the lungs and act as expectorants and reduce cholesterol. Saponin glycosides can cause hemolysis in large amounts but when used normally are extremely safe.

Sterols and sterolins are fats, also known as phytosterols, present in all plants, fruits and vegetables and are chemically similar to cholesterol. Beta sitosterol is the major phytosterol in higher plants and Beta sitosterolin is its glycoside. Animal studies have demonstrated that phytosterols have anti-inflammatory and antipyretic, antineoplastic, glucose-lowering, and immune-modulating activity.

Tannins are generally astringent in nature due to their ability to bind protein and other molecules. They are found in many herbs including Oak bark, Black tea, Blackberry, Witchhazel, Oak galls, black tea and witchhazel. They are used as astringents for wounds, have styptic activity; anti-inflammatory and anti-ulcer action in the gastrointestinal tract and are valuable in the treatment of diarrhea.

Volatile oils are found in aromatic herbs and include the common kitchen herbs such as peppermint, lemon balm, fennel, rosemary, cardamom and cinnamon. They are variously used to stimulate digestion and reduce flatulence (carminatives) and have shown spasmolytic activity on tracheal and gastrointestinal smooth muscle; expectorant activity affecting mucociliary clearance, anti-inflammatory activity, and antiseptic activity.

Studies on single herbs or constituents support the traditional use of herbs, but this only gives a partial view of their medicinal value since traditionally herbs are used in mixtures. While knowing something about the active constituents of herbs is important, herbalists think of plants as more than the sum of their constituents and we avoid considering a researched "active constituent" as being the central reason for a plant's efficacy.

There is much more to it! In fact the art and science of herbal medicine involves a complex individualized therapeutic intervention where the actions of individual herbs are employed together in a formula to alter the underlying physiology of the patient. Herbs can be thought to work through their scientifically supported pharmacological actions, their traditional "actions", and in modern phytotherapy, a combination of these two understandings.

WHAT IS THE SCIENTIFIC PROOF OF THE EFFICACY OF WESTERN HERBAL MEDICINE?

Contrary to what many veterinarians may imagine, there are hundreds of rigorous clinical studies on herbs in the literature, essentially in human medicine, with a small and growing number in veterinary herbal medicine. But this volume of data is still small considering the multitude of herbal medicines being used worldwide with several thousand different plants being used for medicinal purposes. A recent overview included 23 systematic reviews of rigorous trials of herbal medicines. Eleven came to a positive conclusion, nine yielded promising but not convincing results, and three were negative. The relative paucity of rigorous clinical trials is mostly due to the fact that, compared with the pharmaceutical sector, the herbal industry is small and can rarely afford the considerable expense of a clinical trial.

However, numerous randomized double-blind clinical studies have been undertaken on single herb extracts since the 1980s, mainly in Germany. Meta-analyses have been undertaken on the herbs *Ginkgo biloba,* St. Johns Wort (*Hypericum perforatum*), and Saw palmetto (*Serenoa repens*) as examples. Gingko leaf extract was developed in the 1950s in Germany to treat memory loss. This use is now supported by pharmacological evidence as well as clinical trials, and more recently its use in cognitive dysfunction in dogs has also been supported

These clinical studies combined with an enormous number of laboratory studies both in vivo and in vitro on herbs and herbal extracts, explain the mechanisms of action and efficacy for a large number of herbs. There have been a surprising number of research studies performed on cats, dogs and some large animals, and thousands on rats, mice, rabbits and guinea pigs. In *Veterinary Herbal Medicine*, published in 2006, there are over 800 citations made in the Chapter "A Systems Based Approach," referencing clinical trials and in vivo and in vitro studies supporting the use of particular herbs for particular conditions. In the chapter "Herbal Medicine in Equine Practice," there are more than 70 citations; in "Phytotherapy for Dairy Cows" more than 45 citations and in "Ethnoveterinary Medicine" there are some 140 citations. These represent just some of the research base that is published and does not take into account the published research on individual herbs and their activity and pharmacological basis. There is also a body of published research in journals in France, Italy, Germany, India, China, and elsewhere in the world. The extent of the available information and quality of the information is difficult to judge due to language and access constraints.

Many of the published efficacy studies are available on Pub Med or Medline available on www.ncbi.nlm.nih.gov/entrez. Authoritative reviews of herbal efficacy can be accessed in the Cochrane reports at www.update-software.com/publications/cochrane and The European Scientific Cooperative on Phytotherapy (ESCOP) www.escop.com is an international network of scientists and physicians, who have published material submitted to the central European medicines regulatory authorities. Another database that ranks herbal efficacy according to the rigor of the studies is available on www.phytotherapy.info. Many of these studies confirm that whole plant extracts have more than a dietary supplement effect, that they can have efficacy on a particular disease and set of symptoms.

It is likely, however, that the efficacy of herbal medicine is still underrated as problems with clinical research in herbal medicine can include using doses that are much smaller than in traditional herbal medicine (Echinacea for colds is one example where research doses are much smaller than those used by herbalists) and using the same herb or herbal combination for a particular disease when the philosophy of herbal medicine is to treat the individual patient, aiming to improve overall physiology rather than to treat the disease as such.

DEVELOPING AN EVIDENCE BASE FOR VETEINARY HERBAL MEDICINE

How do we resolve the dilemma between the traditional approach to individualizing herbal medicines for animal patients and developing an evidence base? The randomized controlled trial (RCT) is considered the "gold standard in medicine in veterinary medicine. Evidence-based veterinary medicine (EBVM), focused on the double-blinded, randomized clinical trial and systematic reviews has recently been advocated for the veterinary profession. However, there are only a small number of doubled-blinded, randomized clinical trials or systematic reviews published in the veterinary medical literature, which means veterinarians may need to rely on less valid research, such as uncontrolled clinical trials, case series, case reports, or observational studies.

There are some ways in which the evidence base for veterinary herbal medicine can be advanced practically and in a clinical setting. The first are case reports that can provide observational evidence to support veterinary herbal medicine. Case reports are relatively low on the evidence base; however, they should provide both a scientific and a traditional rationale and justification for the therapeutic intervention. Auditing of chronic cases presented to a veterinary clinic, with the same diagnosis using the patient as a control (treatment with conventional medicine then treatment with herbal medicine as a complementary or alternative) might be useful, and this is certainly how veterinary herbal medicine seems to be progressing at the moment.

Another opportunity is involvement in clinical trials. The main challenge to veterinary herbalists is that herbal medicines are individualized. However, a model developed by Bensoussan et al may be valuable to consider. They randomly allocated 116 patients to receive wither a placebo, a standard Chinese medicine prescription or an individualized Chinese herbal prescription for irritable bowel syndrome. Patients were evaluated by both a gastroenterologist and a Chinese medicine practitioner at baseline and at outcome 16 weeks later. Patients on the active treatment showed improvement compared with placebo patients. Individualized and standard treatment showed no difference at the end of the study; however, follow up 14 weeks after the trial showed patients on individualized treatment maintained their improvement while those on standard treatment did not. Based on this model, a study on osteoarthritis of the knee was conducted in patients randomized to receive either Western herbal medicines, either a standard formula or individualized treatment, or placebo. Patients were given nutritional advice, joint supplements, and continued on their conventional medicines. There were clinical improvements in all groups; however, there was significant clinical improvement at outcome compared with baseline for those taking herbal medicine compared with placebo. This model could be used to investigate patient-orientated outcomes in veterinary herbal medicine, even in patients taking conventional medicines.

Examples of published research on animals, not rabbits, guinea-pigs, mice, rats and monkeys (of which there are many more), are listed in Table 1.

References are available from the author upon request.

Table 1. Published Reports on Veterinary Use of Herbal Medicines*

Herb investigated	Type of study	Researchers	Outcome
Aloe vera	Rabbits with induced frost bite Compared with pentoxifylline	Miller, 1995	Comparable to efficacy of pentoxifylline
Aloe vera	Dogs with induced foot pad wounds Compared with antibiotic cream	Swaim, 1992	Aloe stimulates early wound healing to day 7
Aloe vera	Horses with grass sickness Compared with acetylcysteine and brotizolam	Fintl, 2002	None had a beneficial effect on survival
Astragalus	Chickens infected with Eimeria tenella Chickens infected with *Mycoplasma gallisepticum* and compared with apramycin	Guo, 2004 Gou, 2004	Enhancement of cellular and humoral responses compared to controls Stimulated beneficial bacteria and reduced harmful bacteria compared with apramycin
Atractylodes	Chickens vaccinated against Newcastles disease	Ma, 2003	Serum antibody titers significantly increased compared with controls
Berberine (from Barberry)	Dogs with leishmaniasis	Ahuja, 1993	Weekly intralesional injections highly effective against cutaneous leishmaniasis
Boswellia 400mg/10kg	Prospective open multicenter clinical trials, dogs with osteoarthritis No placebo	Reichling et al, 2004	40–70% dogs symptom free
Chaste Tree	Horses with hyperadrenocorticism Clinical trial, no placebo	Self, 2003	Reduction in clinical signs
Chaste Tree	Horses with hyperadrenocorticoism Clinical trial, no placebo	Beech, 2002	No improvement
Cordyceps	Chickens as substitute for growth promoters Compared with avilamycin	Koh, 2003	Similar to avilamycin but improved bacterial population in small intestine

Table 1. Continued.

Echinacea	Pigs, compared with Mecadox control	Holden, 2002	Increased feed efficiency and growth
Echinacea	Pigs, antibody response to porcine reproductive and respiratory syndrome virus, randomized, controlled	Hermann, 2003	No difference
Echinacea	Horses, hematological parameters, double-blind placebo controlled		Increased circulating lymphocytes and neutrophils
Echinacea	dogs with chronic respiratory signs expected to persist for at least 8 weeks, multicenter open clinical trial, no placebo	Reichling, 2004	92% of the dogs had 'good' or 'very good' improvement at 4 weeks
Fenugreek	Dogs with induced diabetes	Ribes, 1986	Lowered blood and urine glucose, improved glucose tolerance
Garlic	Dogs	Dixit, 1980	Reduced cholesterol, triglycerides, phospholipids
Ginger	Dogs, cisplatin-induced vomiting	Sharma et al, 1997	Reduced vomiting, comparable to graniseton
Gingko	Dogs with cognitive dysfunction, open multicenter trial	Hielm-Bjorkman et al, 2006	Improved cognition
Guggal 25mg/kg	Dogs, laboratory study	Dixit, 1980	Lowered cholesterol and triglycerides
Lavender (oil)	Dogs with travel-induced excitement, clinical trial, cross-over controlled	Wells, 2006	Reduced symptoms
Marshmallow	Cats, induced coughing compared with prenoxdiazine, dropropizine	Nosal'ova, 1992	Inhibited cough
Milk Thistle	Chickens, amanita-induced poisoning, controlled	Tedesco et al	Hepatoprotective against aflatoxins
Milk Thistle- silymarin and silibinin	Beagles, compared with prednisolone and cytochrome C	Floersheim, 1978	Hepatoprotective against amanita-induced poisoning compared with drugs
Milk Thistle	Dogs with giardia, compared with metronidazole and combined with metronidazole	Chone, 2005	Combination with metronidazole improved rate of clearance of infection, and did not experience weight loss
Milk Thistle	Beagles, controlled	Vogel et al, 1984	Hepatoprotective
Polyporous 500mg daily (Zhi Ling San)	Cats with induced FLUTD, controlled	Buffington et al, 1994, 1997b	Decreased struvite crystalluria and hematuria
Saw palmetto	Dogs with asymptomatic benign prostatic hyperplasia, placebo controlled	Barsanti, 2000	No positive effect discerned
Schisandra	Horses, one dose 30 minutes before exercising, double-blind crossover	Hanke, 1994	Treatment group had reduced HR and RR, increased glucose and decreased lactate
Schisandra	Chickens vaccinated with Newcastle's disease Controlled, compared with Bacitracin	Ma, 2003	Serum antibody titers significantly increased compared with controls
Tea tree (oil) emulsion	Dogs with dermatitis, open multicenter trial	Fitzi, 2002	Significant improvements observed

Table 1. Continued.

Tee tree (oil) cream	Dogs with focal dermatitis, Practitioner-blinded multicenter trial	Reichling, 2004	Clinical improvement observed
Turmeric	Dogs envenomated with non-lethal doses of snake venom Compared with antivenom and flunixin	Jarcome, 2002	No difference between topical turmeric for local effects compared to antivenom (IV), both better than flunixin
Valerian	Cats, gastric lavage, study design unknown	Von Eickstedt, 1969	Significant decreases in restless, fearful and aggressive behaviors
Varuna (Crataeva)	Dogs, study design unknown	Deshpande, 1984	Significant increase in bladder tone

HERBAL MANUFACTURE — HOW HERBAL MEDICINES ARE MADE & HOW DO I KNOW IF THE HERBS ARE SAFE TO PRESCRIBE?

Barbara Fougere, BSc, BVMS (Hons), BHSc (Comp Med), MODT, MHSc (Herb Med), CVA, CVCP, CVBM
College of Integrative Veterinary Therapies
All Natural Vet Care, Sydney, Australia

WESTERN VETERINARY HERBAL MEDICINE

A plethora of products are available on the market. Why wouldn't we simply recommend that our clients go and buy one off the health food shop shelf for their animal? Quite apart from the standard practice of prescribing according to individual needs, one of our main concerns is whether the practitioner can be confident of product quality. Is it safe? Will it be effective? This article will help you know what questions to ask to make sure you have the right medicine!

HERB VARIABILITY

Compared with well-defined synthetic drugs, herbal medicines exhibit some marked differences, namely:

- They are defined biologically rather than chemically
- The active principles are frequently unknown
- Standardization, stability, and quality control are feasible but problematic
- The availability and quality of raw materials are very variable

All these factors mean that products from different manufacturers or even the same manufacturer of the same plant species, can vary markedly in quality depending on cultivation practices. Diurnal and seasonal variations affect the chemical accumulation in both cultivated and wild plants, and depending on the plant, accumulation of chemical constituents can occur at any time during the various stages of growth. Differences in water availability, fertilizer type, season, light exposure, nutrients, period and time of collection, method of collecting, drying, packing, storage and transportation of raw material, age and part of the plant collected can greatly affect the quality and consequently the therapeutic value of herbal medicines.

The implementation of good herb agricultural and harvesting practices is the first step in quality assurance and also plays a role in preserving the natural resources of medicinal plants for sustainable use. Commercial herbal manufacturers pull herbs from two main sources: wildcrafting and cultivation. Cultivated plants are specifically grown for the trade and are the best sources of endangered or threatened herbs, although herbalists usually prefer wildcrafting since herbs are believed to have greater "vitality" and less likely to be contaminated by pesticides and chemical fertilizers. Wildcrafting, however, is not ideal since it has led to the endangerment of a number of herbs, including goldenseal and ginseng. The impact of cultivation and collection on the environment needs to be considered. Organic cultivated herbs offer a good compromise.

The best advice for minimizing the effect of variability of products on patients is to find a reputable herbal company that manufactures according to Good Manufacturing Practice (GMP) standards, and then to use those herbal products consistently, so that you get to know the medicines well. It is important to know that the herb company you choose complies with these standards, which also ensures that the right species of herb is being used, that it is being produced and stored properly, and that it is not going to be contaminated or adulterated.

GOOD MANUFACTURING PRACTICE

The manufacture of herbal medicinal products should be undertaken according to Good Manufacturing Practice (GMP), since the Code of GMP is not applied to growing, harvesting, drying or sifting of herbs, or preliminary processing of herbal oils. Quality control through GMP is the main way to achieve a high degree of consistency for a manufacturer's products. GMP will also assist in avoiding misidentification and will ensure (as much as the code of practice is adhered to) that the herbal products will be not only safe but also therapeutically potent. However, even if a company does manufacture according to GMP, quality can still vary depending on how well they adhere to the standards and also the quality of the raw ingredients.

One of the critical issues is identification of the plant species. Substitution of one herbal raw material for another can be a serious safety issue, either when it is a sub species, the wrong species (eg, Aristolochia for Stephania causing renal failure), or a less active plant part, or when a herb is contaminated with another species (eg, Digitalis in Comfrey). Herbs have been known to be contaminated with heavy metals (eg, cadmium) and also adulterated with drugs (eg, prednisolone). Any contamination could compromise the safety and efficacy of a herbal preparation. The starting materials for herb manufacture therefore require specifications for crude plant material that includes information on the source, part used, description, identification, and reports on contamination with pesticides, microbes, mould, pests or foreign matter and purity or potency.

While the source and quality of raw materials play a pivotal role in guaranteeing the quality of the product, variations in therapeutic properties and safety can still occur during manufacturing since stability of plant chemicals can also vary. Some plant constituents are heat labile and the plants containing them need to be dried at low temperatures. Also, other active principles are destroyed by enzymatic processes that continue for long periods of time after plant collection. While the final product can be tested for stability using analytical markers; it is impossible to test for all phytochemicals in the product which could degrade at different rates. These factors account for variability of markers and active constituents in herbal preparations.

Standardization

There is a general trend towards the marketing of "standardized" herbal medicines. Advances in the processes of purification, isolation, and measuring certain phytochemicals have made it possible to establish appropriate strategies for the analysis of quality and the process of standardization of herbs in order to maintain as much as possible the homogeneity of the plant extract (Table 1). Among others, gas chromatography, high-performance liquid chromatography, thin-layer chromatography, mass spectrometry, infrared-spectrometry, and ultraviolet/visible spectrometry, used alone or in combination, can be successfully used for standardization and to control the quality of both the raw material and the finished herbal products.

Herbalists have some issues with standardization, though. Plants contain many constituents and some of them are present at very low concentrations and despite these technologically advanced chemical analytical procedures, rarely do phytochemical investigations succeed in isolating and characterizing all the secondary metabolites present in the plant extract. Also, marker substances used in standardization and quality control tests may not even really account for the therapeutic action reported for the herbal products. So we may be standardizing to one constituent, which does not actually measure the quality or efficacy of the whole product.

Tinctures

Herbal products come in many forms, from fresh, dried, tableted, powdered, tinctures, creams and gels to name just a few. Herbal tinctures are used by most herbalists, since they allow tailoring for individual patients and their conditions.

Tinctures are the most commonly dispensed liquid forms of herbs; combining liquids makes formulation and prescribing easy. Benefits include:

- Alcohol based (solvent, preservative 25% to 45%), so good shelf life and excellent bioavailability
- Concentrated – small doses can be mixed in with food
- Convenient – can blend different herbs together easily

Animals hate the taste of alcohol, but the small doses mean the taste can easily be disguised. Glycetracts are often manufactured by first extracting in alcohol, reducing the alcohol, and preserving in glycerin, which produces a more palatable product, but with a shorter shelf life. Alcohol is a useful solvent and forms tinctures with nearly unlimited shelf-lives. The percentage of alcohol needed varies according to the constituents to be dissolved, and good manufacturers vary the alcohol:water ratio to reflect the ideal extract for each individual herb. Tinctures are prepared with use of the herb (the "marc") and a solvent (the "menstruum"). The concentration of a tincture is expressed as a weight:volume ratio (w:v), that is, the weight of dried herb used to the volume of menstruum/solvent added. For example, a 1:3 product means 1 gram herb in 3 mL. This makes dosing more precise. If you want your patient to receive 0.5 grams of this herbal medicine, they would need to be given 1.5 mL of the medicine.

In the industry, two main methods are used to make tinctures and fluid extracts: percolation and maceration.

Percolation

Ground dried herb is soaked in the menstruum (solvent) for several hours. The swollen plant material is then packed into a percolator, which is a tall metal or glass cylinder. More menstruum is added to cover the plant material, and this is left to macerate for 24 to 48 hours, and sometimes for weeks, depending on the herb. The tap at the bottom of the percolator is opened to allow a slow drip, and the percolate is collected in a closed container. A number of more complicated processes are used commercially to make more concentrated extracts.

Some manufacturers make very concentrated extracts by reducing the volume of liquid under partial vacuum, then diluting in another liquid. This usually involves heat; therefore, extracts made in this way are generally considered to be of inferior quality because of the potential for heat damage to some of the constituents.

Table 1. Some Popular Herbs and Their Typical Marker Substances*

Herb*	**Standard(s)**	**Category**
Asian Ginseng (*Panax ginseng*)	Ginsenosides R_{g1}/R_{b1}	M
Devil´s Claw (*Harpagophytum procumbens*)	Harpagoside, Harpagide	M
Kava Kava (*Piper methysticum*)	Kavalactones	AS, M
Milk Thistle (*Silybum marianum*)	Silybin/Silydianin	AS, M
St. John's wort (*Hypericum perforatum*)	Hyperforin, Hypericin	M
Ginkgo (*Ginkgo biloba*)	Bilobalide, Ginkgolides	M

* The marker substances are based on their use for quality control purposes and/or because they are known active compounds. M = marker AS = proven active substance.

** *National Formulary* (published by the United States Pharmacopeia, 21st edition)

Maceration

Dried herb is soaked (macerated) in the desired menstruum at room temperature for a time. The final menstruum is allowed to settle, decanted and filtered. This process is suitable for small-scale production of tinctures.

HERB SAFETY AND ADVERSE EVENTS

Once you are satisfied that you have a quality product from a good manufacturer, how do you know it is safe? Even though herbal medicines are not without some risk,[1] they could still be safer than conventional drugs, at least in humans. The World Health Organization's monitoring center collected 8,985 reports of adverse events associated with herbal medicines from 55 countries between 1968 and 1997.[2] These were associated with a variety of explanations including inadvertently using the wrong plant species, adulteration with drugs or toxic plants, contamination with heavy metals, over dosage, interactions with drugs, inappropriate self-prescribing, or inappropriate prescriptions by practitioners. Although this number may seem impressively high, it amounts to only a tiny fraction of adverse events associated with conventional drugs held in the same database.[2]

However, the relative paucity of adverse events could also be due to a relatively higher level of under reporting.[3] More conclusive evidence on the relative risks of herbal medicine versus conventional drugs is scarce. Linde et al showed that the herbal antidepressant St. John's wort was reported to have half the rate of adverse effects compared with conventional antidepressants.[4] Kava, an effective herbal anxiolytic,[5] has been banned recently in several countries because of suspected (rare) hepatotoxicity, yet preliminary data indicate that it probably is still safer than benzodiazepines.[6] Currently the relative safety of herbal medicines is not defined, but indications from the existing data, suggest that adverse events, particularly serious ones, occur less often than with prescription drugs.[7]

The use of herbal medicines and Internet sales for the prevention and treatment of a variety of illnesses in small animals has increased tremendously in recent years and it is expected that adverse events will occur. Whereas most herbal remedies, when used as directed and under the supervision of knowledgeable practitioners are safe, the potential for adverse effects or intoxications certainly exists.[8] Adverse events reported in animals include those horses testing positive for caffeine after being given products containing guarana and ginseng or ephedra, and toxicosis in dogs given similar products, toxicosis in cats and dogs with melaleuca oil and garlic as well as chamomile in cats.[9] Adverse events should be reported to www.vbma.org.

Some herbs have a very small safety margin and should not be used unless there is no other alternative (examples include herbs used in veterinary medicine in the 1800s, such as hemlock, foxglove, aconite, and others) and herbs such as comfrey, which are excellent externally but toxic internally. In addition, there is a degree of concern for potential herb drug interactions in veterinary medicine based on issues in human herbal medicine.

CONCLUSION

In order to minimize risk and maximize safety, veterinarians need to be aware of those herbs with low safety margins, and be cognizant of potential herb-drug interactions. There are a number of evidence-based resources available to assist veterinarians in the safe use of herbal remedies such as www.pubmed.org and www.naturaldatabase.com as well as Herbal Medicine Potential for Intoxication an Interaction with Conventional Drugs by Poppenger.[9] By using good quality herbs, and by prescribing the right herbs for the patient at the right doses, those herbs will be have a high safety margin and be safe to prescribe.

HERBAL MEDICINE FOR COMMON CONDITIONS

In Western Herbal Medicine, we see several schools of thought about herbal remedies. One school uses formulas that may have four to six or more herbs and most present-day herbalists take this approach. This reflects the true power of herbal medicine, which when prescribed for the individual patient, can effectively treat chronic conditions. It does this by fundamentally changing the physiology of the patient. The other approach is to use "simples," where one or two herbs are taken in larger doses. There is certainly a move towards the use of single herbs. However, this is more to do with Western Herbal Medicine following conventional medicine's approach to treatment—for example, using Echinacea's immune modulating activity for a cold, ginger's antiemetic action for nausea, or St. Johns Wort for mild depression. The availability and use of standardized extracts follows this approach and herbs are promoted for their drug-like effect in dealing with specific problems. Standardized extracts are manufactured to provide natural alternatives to the drugs used by Western medicine. And this trend is also happening in veterinary medicine—for example, *Ginkgo biloba* has recently been shown to be useful for cognitive dysfunction in dogs.

On the other hand, "singles" do lend themselves to acute prescribing, for simple conditions in otherwise healthy patients. Using single herbs is also a good training ground for beginning veterinary herbalists to learn these medicines by using them one at a time and understanding their uses and potential. They are relatively easy to integrate into practice in order to offer a "natural" alternative or complementary medicine for patients. In this article, we look at some simple uses of herbs (some of my personal favorites) and their biomedical actions and conditions for which they can be exploited. You should be able to integrate and use them safely and for a multitude of purposes.

CHAMOMILE *Matricaria recutita*

- **Parts Used:** Dried flowers
- **Energetics:** Hot, dry
- **Clinical Actions:** Carminative, spasmolytic, mild sedative, nervine, cholagogue, antiallergic, anti-inflammatory, vulnerary, bitter tonic, antimicrobial
- **Traditional Usage & Indications:** minor diarrhea, to relieve eye strain, a spasmolytic and sedative tea, wash for minor wounds, loss of appetite, gastric ulcers, teething, motion sickness, inflamed skin. The uses may seem too many to be true, but reflect the broad activity of chamomile's constituents in the body.
- **Published Research:** Inhibits both cyclo-oxygenase and lipoxygenase, anti-inflammatory, antispasmodic, beneficial in the treatment of radiation mucositis, demonstrates anxiolytic activity.
- **Potential Veterinary Indications:** Used internally, it is probably one of the best known relaxing nervines for anxiety, especially when associated with digestive issues. German Shepherds with stress-induced diarrhea respond very well. Other animals with mild diarrhea can be given chamomile by mouth or added into food. Animals can be bathed in it. It has mild antimicrobial action. Also useful as an eye wash for mild conjunctivitis or used for topical wound therapy as a spray. Use as a wash for pruritic mice and rats. It can be added to food to reduce odor in goat's milk. Inhaled as essential oil, it can relieve nasal inflammation and sinusitis.
- **Contraindications & Toxicology**: Allergy to plants of the Asteraceae (Compositae) such as ragweed, asters, and chrysanthemums. Epistaxis and subcutaneous hemorrhage have been reported in cats associated with chamomile use.
- **Preparation & Dose:** External use: compresses, baths, rinses: 15–50 grams flower/500 mL water, steep 15–30 minutes. Vapor inhalation, 1–5 drops per liter of water. Infusion for dogs 5–30 grams per cup of water, give ¼–½ cup per 10 kg divided daily by mouth or in food. Tincture (1:2) 0.5–1.5 mL per 10 kg divided dose.

TURMERIC *Curcuma longa*

- **Parts Used:** Dried rhizome
- **Energetics:** Warm, pungent
- **Clinical actions:** Anti-inflammatory, stimulant, tonic, carminative, anthelmintic, antioxidant, antiplatelet, cholagogue, hepatoprotective, anticancer, cholesterol reducing
- **Traditional Usage & Indications:** Arthritis, diarrhea, epilepsy, pain, skin diseases, acid, flatulence, or atonic dyspepsia, prevention of cardiovascular disease and cancer; arthritis, asthma, eczema, to improve GIT and liver function.

  Ethnoveterinary uses: Ulcers, ticks, castration wounds, bleeding, eye disorders and fungal diseases, diarrhea, rheumatism, worms in poultry, constipation, udder infection, swollen teats, sprains, coughs and colds in ruminants and poultry, jaundice and for swine pox.
- **Published Research:** Most research has taken place in India and has focused upon turmeric's active curcuminoids (the most well known being curcumin) and volatile oil. The curcuminoids are an important class of antioxidant and anti-inflammatory constituents and are responsible for turmeric's vibrant yellow color. In human clinical trials, the constituent curcumin has been shown as effective as NSAIDs, without the side effects. Although the mechanism of action is not fully understood, turmeric's anti-inflammatory actions are thought due

to its ability as an antioxidant to quench free radicals, hindering tissue degeneration and its ability to inhibit the arachidonic acid cascade. Turmeric has been investigated for its antibacterial, antiparasitic, choleretic, antiviral, antiplatelet, analgesic, antioxidant, anticancer, antihepatotoxic, and antitumor effects.

- **Potential Veterinary Indications:** A paste can be applied externally to sores, wounds, bruises, bites, inflamed joints, small tumors. A decoction (25 g of the bruised root to 500 mL of water) can be applied as a lotion to relieve discomfort in conjunctivitis and other eye inflammations. As a substitute for NSAIDs, turmeric can be used with or instead of NSAIDs for pain or injury. More chronic conditions include chronic anterior uveitis, as an adjunct to cancer treatment or prevention, arthritis, skin disease, liver disease.
- **Contraindications & Toxicology:** Obstruction of the biliary tract. Hypersensitivity to turmeric. **Preparation & Dose:** Powder can be mixed with water (1 teaspoon powder to one of water) as a paste for topical application. It can be added to food to tolerance (¼–1 tsp); or ground, macerated root, 1 tsp in water added to food (¼–½cup per 10 kg). Cat 50–100 mg curcumin qid, Dog 50–250 mg curcumin tid. Tincture (1:2)1.0–3.0 mL per 10 kg.

GREEN TEA *Camellia sinesis*

- **Parts Used:** young leaves
- **Energetics:** warming, drying
- **Clinical Actions:** Stimulant, antioxidant, possible antimutagen
- **Traditional Usage:** Stimulant, diuretic, astringent and to improve heart health, flatulence, promoting digestion and improving mental processes.
- **Published Research:** Green tea extracts have been used to prevent cancer including breast, stomach and skin cancer; can increase mental alertness (contains caffeine), is anti-inflammatory, antioxidative, antimutagenic, and anticarcinogenic, has been used in the treatment of childhood atopic dermatitis, may be prophylactic for arthritis, antidiarrheal
- **Indications:** Prophylaxis against cancer, stimulant, diarrhea, arthritis, atopy
- **Potential veterinary uses:** Can be made into tea and used internally and externally. As a mouth wash it can be used after dental procedures, for flushing oral surgery, oral tumors, sore throats. Can be given internally for mild diarrhea, for cancer prevention, for adjunctive cancer therapy
- Topical tea for hot spots, as a bath for atopic dermatitis and rashes
- **Contraindications & Toxicology:** Caffiene. Avoid using large amounts in cardiovascular and renal disease, thyroid hyperfunction, or anxiety. Overdose can lead to hyperacidity, gastric irritation, reduced appetite, obstipation, or diarrhea.
- **Preparation & Dose:** 1 tsp per cup of water, ¼–1 cup per 10 kg. Can be added to food, water, or syringed in mouth

BILBERRY *Vaccinium myrtillus*

- **Parts Used:** The ripe fruit and leaves
- **Energetics:** Cool, dry
- **Clinical Actions:** Vasoprotective, antioxidant, anti-inflammatory, astringent, antiedema
- **Traditional Usage & Indications:** Bladder stones, biliary disorders, scurvy, coughs, and lung disease diarrhea, dysentery and mouth and throat inflammations, to lower blood sugar in diabetes, nerve tonic for animals. Retinal damage, night blindness, capillary fragility
- **Published Research:** Anthocyanidins, protective effects in endotoxic shock, antiulcer activity, decreased plasma triglycerides and cholesterol levels, hypoglycemic, significant vasoprotective and antiedema properties
- **Potential Veterinary Indications:** PRA, nuclear sclerosis, herbal antioxidant, geriatric patients as antioxidant support. As a tea for diarrhea
- **Caution:** Antiplatelet aggregating properties
- **Preparation & Dose:** Fresh berries 5–100 g tid, tincture 1:2, 0.5–1.5 mL per 10 kg divided. Dried herb 25–300 mg/kg divided. Standardized extract (25% anthocyanidins) 2–4 mg/kg divided dose.

ECHINACEA *Echinacea purpurea, E. angustifolia*

- **Parts Used:** Aerial parts (modern preparations) or roots (original Eclectic use)
- **Energetics**: Sweet and pungent, or cooling and dry
- **Clinical Actions:** Nonspecific immune support, immune modulating, vulnerary, antimicrobial, anti-inflammatory, vulnerary, alterative, anticatarrhal.
- **Traditional Use & Indications:** Snakebite, stings and other topical uses, chewed for toothaches and mouth sores, and smoked for headache, antiseptic and alterative, treatment of fevers, respiratory infections, local infections , digestive disorders
- **Published Research**: Immune modulating, activates macrophages and increases phagocytosis by increasing WBCs. Reduce inflammation and edema, possibly by inhibiting cyclo-oxygenase and lipoxygenase, improve respiratory infection, treat colds at their onset. Antifungal effects, protects against radiation-induced damage, vulnerary. Inhibits hyaluronidase, thereby improving integrity of connective tissue barrier in wounds. Anticancer.
- **Potential Veterinary Indications:** Viral and bacterial infections, infections (acute and chronic), especially of the upper respiratory tract. As a preventative of contagious canine cough and as a treatment, Catarrhal conditions of the nose and sinus. For gingivitis. Applied externally for wounds, cuts. Food supplement for mice as an anticancer agent.
- **Contraindications & Cautions**: Allergy to members of the daisy family. Theoretically it might interfere with immune-suppressant or other immune-

modulating drugs.

- **Preparation & Dose:** It is most effective when used at first signs of infection. Tincture 1:2, 0.5–1.5 mL per 10 kg divided. Infusion 5–30 grams per cup of water ¼–½ cup per 10 kg divided. Dried herb 25–300 mg/kg divided

MARSHMALLOW *Althaea officinalis*

- **Parts Used:** Dried roots
- **Energetics:** Sweet
- **Clinical Actions:** Demulcent, emollient, expectorant, diuretic, mucilage, anti-inflammatory
- **Traditional Usage & Indications:** Demulcent for coughs and irritations of oral and pharyngeal mucosa ,emollient for wounds and dry skin, to mask the bitter or pungent taste of other drugs, for asthma, cystitis, dysentery and irritations of the gastric mucosa. All inflammatory disorders of the GIT, respiratory and urinary tract. Externally the leaf can be used to draw abscesses out, and as an emollient for ulcers
- **Published Research**: Anti-inflammatory activity, antitussive, antimicrobial against *Pseudomonas* and *Proteus* sp. when used topically
- **Potential Veterinary Indications:** Post extubation, contagious canine cough, geriatric conditions where mucous membranes are inflamed. Acute respiratory disease, gastroenteritis, cystitis, wounds, skin ulcers, abscesses
- **Preparation & Dosage:** Dried leaf 5–30 grams in 1 cup water, ¼–½ per 10 kg divided. Glycetract 1:2, 0.5–1.5mL per 10 kg divided

MILK THISTLE *Silybum marianum*

- **Parts Used:** Seed.
- **Energetics**: Controversial, sweet and cooling & bitter, warm
- **Clinical Actions:** Hepatoprotective, demulcent, cholagogue, galactagogue, antioxidant
- **Traditional Usage & Indications:** Liver disease, splenic or hepatic congestion, to increase lactation; liver disease due to toxins; inflammatory liver disorders; cirrhosis. In cattle, milk thistle may be appropriate in the treatment of ketosis, increasing milk yield and decreasing ketonuria
- **Published Research:** Silymarin is a bioflavonoid complex. Silibinin is thought most active and probably responsible for the benefits attributed to silymarin. It decreases aminotransferase activity, silybin reduces oxidative damage to kidney cells, silybin prevented cisplatin induced nephrotoxicity in rats, but did not prevent cyclosporine-induced glomerular damage except for lipid peroxidation; may inhibit hepatic synthesis of cholesterol and reduce blood lipids; silymarin can protect the pancreas against certain forms of damage.

  Acts as an antioxidant; it inhibits lipid peroxidation in hepatocyte plasma membranes, thereby protecting against many toxins; it protects against genomic injury by suppression of lipoxygenase, hydrogen peroxide and superoxide; It increases hepatocyte protein synthesis; It stabilizes mast cells and decrease the activity of tumor promoters
- **Potential Veterinary Indications:** Because milk thistle is proven to be a liver herb doesn't mean that it's only a liver herb. Consider it for conditions affecting the spleen, pancreas, liver and kidneys, for subclinical elevations in liver enzymes or mild elevations in renal measures; as an adjunct to potentially hepatotoxic drugs and pre and post anesthesia. Hematuria is also another indication based on traditional use. Consider use in elevated triglcyerides or cholesterol. Giardia in dogs or metronidazole administration.
- **Contraindications & Cautions**: Allergies reported, Milk thistle reduces activity of CYP3A4 and UGT1A6/9 liver enzymes, and may decrease insulin requirements in some diabetics
- **Preparation & Dosage**: Flavonolignans are not very water soluble, so liquid extracts must be alcohol based. In modern phytotherapy a solid extract of the seeds is used, standardized to 70% silymarin content. Milk thistle should be used for at least 8 weeks before expecting results such as improvement in biochemistries. Dried herb 50–100 mg/kg divided, unprocessed seed triple dose. Glycetract 1–2 mL/10 kg divided, dry standardized extract (70% silymarin) 10–15 mg/kg divided

GINGER *Zingiber officinale*

- **Parts Used:** Dried rhizome
- **Energetics:** Hot, dry
- **Clinical Actions:** Stimulant, carminative, antispasmodic, bitter, anti-inflammatory, antiplatelet, diaphoretic
- **Traditional Usage & Indications:** Headaches, nausea, rheumatism and colds. To treat cold extremities, improve a weak and tardy pulse, address a pale complexion and strengthen the body after blood loss, treatment of dyspepsia, flatulence, colic, vomiting, diarrhea, spasms and other stomach complaints. To treat colds and flu, to stimulate the appetite, as a narcotic antagonist and as an anti-inflammatory agent in the treatment of migraine headache and rheumatic and muscular disorders
- **Published Research** Cholagogic activity, hyperlipidemic activity, anti-atherogenic activity, gastrointestinal activity, gingerols are reported to have antiserotoninergic activity and it has been suggested that the effects of ginger on gastrointestinal motility may be due to this; antiemetic activity (peripheral) a direct effect on the gastrointestinal tract by increasing gastric motility and adsorption of toxins and acids , anti-inflammatory activity, cholesterol-lowering, antithrombotic , as effective as ascorbic acid as an antioxidant, inhibits the activities of cyclo-oxygenase and lipoxygenase, for rheumatic pain and chronic lower back pain; gingerols inhibit the growth of *H. pylori;* antidiabetic activity (increase in insulin levels and a decrease in fasting glucose levels in diabetic

rats).

- **Potential Veterinary Indications:** Nausea, travel nausea, chemotherapy nausea, improving circulation in geriatric animals. As an adjunct for arthritis treatment
- **Contraindications & Cautions:** May affect bleeding times, stop 1 week prior to surgery
- **Preparation notes:** Infusion 5 g per 1 cup water, ¼–½ cup per 10 kg divided. 15–200 mg/kg divided of dry powder; Tincture 1:2, 0.25–0.5 mL per 10 kg divided. For travel nausea 30 minutes prior to travel 25–50 mg/kg divided.

HERB–DRUG INTERACTIONS — WHAT YOUR CLIENTS ARE USING AND WHAT YOU NEED TO KNOW

Barbara Fougere, BSc, BVMS (Hons), BHSc (Comp Med), MODT, MHSc (Herb Med), CVA, CVCP, CVBM
College of Integrative Veterinary Therapies
All Natural Vet Care, Sydney, Australia

THE POTENTIAL FOR VETERINARY HERB–DRUG INTERACTIONS

Numerous Web sites and human practitioners are offering products for animal use. While herbal medicine is safe when used appropriately, as more animals are treated with herbs it becomes more likely that we will see herbs interacting with veterinary medications or procedures. Whether these will be clinically relevant, remains to be seen, however they should not be ignored. With some 20% of pet parents using some form of complementary medicine, the concerns are amplified when they self-prescribe for their pets. Asking what they are using should become a normal part of a history, particularly if planning surgery or initiating drug treatment. It's also important to report any suspected interactions, whether positive or negative, so that we can develop a body of veterinary-specific knowledge. This article focuses on potential herb–drug interactions that veterinarians should be aware of.

REPORTED HERB–DRUG INTERACTIONS

There are some very serious herb–drug interactions, as opposed to toxicities, reported in the human literature, especially involving St. Johns Wort and warfarin among others. However, the issue of herb–drug interactions has perhaps been largely over emphasised. One of the major problems has been that until recently the few sources of information about herb–drug interactions distinguished between interactions that were suspected and those that were well documented. Many herb–drug interactions are postulated based on potential pharmacological interactions due to a constituent in the herb, while the actual clinical relevance has not been established. Others interactions include anecdotal reports without essential data to establish a firm cause–effect relationship.

In one review to consolidate the clinical and pharmacologic aspects of drug–herb interactions, data bases were searched from 1966 to 2002. Of 162 citations identified, only 22 citations met the inclusion criteria of being adequately reported. Using a matrix of 165 possible drug–herb interaction pairs (15 therapeutic drug classes by 11 herbal products), the study identified 51 (31%) interactions discussed in the literature. Twenty-two of these 51 drug–herb pairs (43%) were supported by randomized clinical trials, case-control studies, cohort studies, case series, or case studies. The remaining interaction pairs reflected theoretic reasoning in the absence of clinical data. Most interactions were pharmacokinetic, with most actually or theoretically affecting the metabolism of the affected product by way of the cytochrome P450 enzymes. In this review, warfarin was the most common drug and St. John's Wort was the most common herbal product reported in drug-herb interactions.[1] St. Johns Wort is probably the most comprehensively investigated herb for possible interactions with anticonvulsants, digoxin, cyclosporine, theophylline, and other drugs in human medicine.

Several references can be consulted on herb–drug interactions including Poppenger's *Herbal Medicine: Potential for Intoxication and Interactions with Conventional Drugs*,[2] McGuffin et al's *Botanical Safety Handbook*,[3] Brinker's *Herb Contraindications and Drug interactions*,[4] European Scientific Cooperative on Phytotherapy (ESCOP),[5] and the German Commission E monographs.[6] Interestingly, of the more than 600 herbs mentioned by all these resources, only a relatively small number of herbs are implicated in a negative way and most of these are theoretical or speculative concerns. There are also Web sites that can provide up to date information including www.naturaldatabase.com, www.healthnotes.com, www.ncbi.nlm.nih.gov/PubMed.

Veterinary-related suspected herb–drug interactions or adverse events can be reported on the Web site of the Veterinary Botanical Medicine Association www.vbma.org. Reports should include adequate patient history; complete chronology; concurrent diseases, conditions or medications presumably not associated with the adverse event; concurrent medications, diet and supplements; adequate description of interactors; exclusion of obvious explanations other than herb–drug interaction; reasonable time sequence of drug administration to adverse event; cessation of event on stopping the drug or herb; recurrence of event with challenge.

No doubt, however, there are many instances that occur and go unreported. Nonetheless, in this author's experience of daily veterinary herbal practice, herb–drug interactions have not been detrimental. On the other hand, they have been beneficial to the patient in being able to modify potential side effects (using liver-protective herbs, for example), or reducing the dose rates of conventional medications needed, or being able to discontinue medications altogether.

CATEGORIES OF HERB–DRUG INTERACTIONS

It is beyond the scope of this article to discuss in detail the mechanisms of herb–drug interactions. However, they may be broadly classified as:

Pharmaceutical - When compounds interact due to physical or chemical interaction, such as tannins and alkaline drugs.

Pharmacokinetic - Modulation of drug absorption due to altered absorption, distribution, metabolism, or elimination.

Pharmacodynamic – Synergistic, whereby the herbal product potentiates the action of the conventional drug, Antagonistic, whereby the herb may directly antagonize the actions of the drug or a new effect from the combination not anticipated from either alone. The potential for these interactions can to some extent be predicted by knowing the constituents and pharmacology of the herb and the concurrent drug. Many lists of herb–drug interactions have been proposed based on the assumptions of potential pharmacodynamic herb–drug interactions. However, inclusion in such lists does not mean that a clinically important interaction will necessarily occur.

Several authors have further classified herb–drug interactions.[4,7,8,9] Like conventional drugs, the pharmacokinetics of herbs are influenced by factors such as species, age, and disease/health state, and hence there is potential for drug–herb interactions as well as herb–disease interactions. Oftentimes these interactions result in a beneficial reaction. In fact, one of the fundamental tenets of herbal medicine is that interactions occur between the constituents within a single plant, and between herbs in a formula, either to increase desired effects or to reduce unwanted effects or both, but this is not the focus of this article.

PRACTICAL HERB–DRUG CONSIDERATIONS IN VETERINARY PRACTICE

Concerning the potential for interactions, it is also important to consider the variability that exists in products containing the same herbal ingredient, as well as the quality of its manufacture and the dose rates. Being able to quickly calculate the herb dose is an important skill, especially since many pet parents use human products.

Proactive management to reduce the negative consequences of herb–drug interactions or to gain the positive benefits of the same, including having a knowledge of the herb's activity to predict potential issues. Understanding the herb's main constituents, actions and uses is helpful. If there are concerns, separating drugs and herbs by half to one hour or more might be worthwhile. If an owner has an animal on a drug regime and wants to introduce herbs, suggest starting with a low dose and working up slowly.

Preoperative Concerns

The need to discontinue herbs prior to surgery or anesthesia has been proposed based on the potential for herb–drug interactions prior to, during, or after surgery. The minimum period that herbs should be discontinued is unknown; however, a week, if available, seems reasonable. We utilize Milk thistle routinely in the preoperative and postoperative period for our patients to protect against the oxidative stress of general anesthesia. Other helpful herb groups include antimicrobial herbs (eg, goldenseal); antiemetics (eg, ginger); anti-inflammatories (eg, devil's claw, licorice); immune-supporting herbs (eg, echinacea); and tonics (eg, withania). Herbs to avoid in the week before surgery include those which reduce blood-clotting. Potential Increased bleeding can occur with garlic, ginkgo, ginger, dong guai, saw palmetto, and Asian ginseng. We also stop fish oils, vitamin E, and chondroitin. The sedative effect of anesthetics or sedatives can be potentially increased by kava, valerian, ginkgo, goldenseal, and St. Johns Wort. These are often stopped 1 week prior to surgery in humans.

Interference with Diagnostic Tests

While not strictly an herb–drug interaction, some herbs can influence the results of biochemistry or diagnostic tests. For example, human patients taking Siberian ginseng (Eleuthero) have elevated digoxin levels (possibly due to interference with the assay). Bugleweed (*Lycopus europaeus*) in cats can interfere with diagnostic procedures involving radioactive isotopes (author's personal experience).

Patients on Drugs with Narrow Therapeutic Windows

Patients on digitalis, anticoagulants, hypoglycemic agents, and immune suppressants such as cyclosporine should be monitored very closely if herbs are given concurrently.

Patients that are on antiseizure medications, sedatives, tricyclic antidepressants, or anxiolytic drugs along with sedative or nervine herbs need to be monitored and possibly reduced. We have certainly experienced this in our practice.

Many herbs can lower blood glucose, this is primary importance in diabetic animals and they need to be monitored closely; these include aloe, gymnema (*Gymnema sylvestre)*, fenugreek, ginseng, and bitter melon.

Likewise, patients on conventional polypharmacy are at greater risk for interaction in any number of ways, and if they are geriatric, even more so. Take care.

Patients with Compromised Hepatic or Renal Function

Patients on drugs and herbs need to be monitored very carefully. In the author's opinion herbal medicines can greatly improve the biochemical parameters and general health of these patients when prescribed appropriately.

Common Herbs that can Affect Absorption and Metabolism of Drugs

Herb constituents such as fibers and mucilages can reduce gastrointestinal absorption of drugs; examples include flax seed, marshmallow, and slippery elm. Similarly, high tannin-containing herbs such as agrimony can reduce the absorption of alkaline drugs.

Laxative herbs such as aloe *(Aloe* spp.), buckthorn *(Rhamnus frangula)*, cascara sagrada *(Rhamnus purshiana)*, and rhubarb *(Rheum* spp.) could potentially reduce absorption because of reduced gut transit time.

Licorice can increase the risk for potassium depletion when used with diuretics or corticosteroids.

Echinacea, gingko, garlic, licorice, milk thistle, and valerian are metabolized by cytochrome P450 enzymes and can influence metabolism of glucocorticoids, phenobarbital, ketaconazole, midazolam, and calcium channel blockers.

Uva ursi or bearberry leaf *(Arctostaphylos uva-ursi)* should not be administered with any substances that cause acidic urine, such as ascorbic acid and ammonium chloride, as it will reduce the antibacterial effect.

Ginger, cayenne, black pepper, and prickly ash can increase bioavailability of drugs.

Herbs that Can Protect Against Adverse Side Effects of Drugs

1. Several herbs can protect against the adverse effects of drugs on stomach and liver, including licorice, milk thistle *(Silybum marianum)*, bupleurum, and ginger *(Zingiber officinale)*. Milk thistle reduces liver enzymes in dogs on phenobarbitone (personal experience).
2. Milk thistle decreases hepatotoxicity of drugs such as halothane and phenytoin, and nephrotoxicity of anesthetics, cisplatin, and doxirubicin without reducing activity.
3. Several herbs can lower the required amount of conventional drug needed because of similar action such as licorice and prednisolone, hawthorn, and cardiovascular drugs (Hawthorn can increase the effects of cardiac glycosides while protecting against harmful effects), nettle leaf and antihistamines, astragalus and chemotherapeutics.

Basic Guidelines to Minimize Potential for Herb–Drug Interactions

Like any conventional medicine, the use of medicinal herbs must be monitored carefully. Herbs can be combined with conventional medicines but must be monitored as the dose rate required for medicines can change. Obtain herbal products from companies that have good quality control measures so that consistency is more likely. Aim to use a dosing strategy that is consistent so that you get experience with efficacy, safety, and interaction with drugs.

CONCLUSION

As part of the patient intake, ask pet parents what they might be using on their animals. It is particularly important for patients about to undergo surgery but also for patients that are diabetics, on cardiovascular drugs, anxiolytic drugs, and patients with epilepsy or gastrointestinal disease. Most herb–drug interactions are only a potential; however, it is important to monitor medicines carefully, and to report suspected interactions- both negative and positive! If you are inexperienced with herbal medicine and would like some help, contact www.vbma.org.

HERBAL MEDICINE IN PRACTICE — DISEASE MANAGEMENT WITH ANTIOXIDANT HERBS

Barbara Fougere, BSc, BVMS (Hons), BHSc (Comp Med), MODT, MHSc (Herb Med), CVA, CVCP, CVBM
College of Integrative Veterinary Therapies
All Natural Vet Care, Sydney, Australia

In recent years there has been an increased understanding of the importance of oxidative damage in both the pathophysiology of disease and the aging process in all species. This review will describe several herbs with antioxidant activity and where they are most likely to have therapeutic activity as antioxidants in the prevention and treatment of common veterinary conditions.

BACKGROUND

A free radical is any atom or molecule that contains one or more unpaired electrons. The simplest free radical is an atom of the element hydrogen; however, there many others including superoxide, hydroxyl, thiyol, and peroxyl. Singlet oxygen is also a contributor to oxidative stress, even though it is not a free radical, so the phrase "reactive oxygen species" (ROS) is often used to encompass all the species capable of causing oxidative damage. ROS are produced naturally in as a consequence of metabolism as well as pathological processes. New evidence is emerging to suggest that the ROS can act as signalling molecules in the regulation of gene expression, cell growth and cell death.

In situations where the generation of oxidative species is increased, antioxidant defenses may be insufficient to cope, and the result is oxidative stress. Oxidative stress represents an imbalance between oxidants and antioxidants in favor of oxidants. It results in damage to lipids (eg, phospholipid membranes) via lipid peroxidation, nucleic acids (eg, leading to carcinogenesis), and proteins damage. While the inherent biological array of mechanisms to prevent oxidative damage is impressive, it can be overwhelmed. As well as the ROS generated in everyday life other factors can increase the radical species which have the potential to attack cellular components. These factors include exercise, inflammation, environmental pollution, UV light, certain drugs, anesthetics, and radiation. For example, studies carried out in racing greyhounds and sled dogs has shown that they undergo oxidative stress with exercise. Oxidative stress has also been shown to occur in normal healthy adult dogs after about 20 minutes of exercise and research has demonstrated that oxidative stress is also induced by the administration of general anesthetics and sedation in dogs.

Oxidative stress and damage to cells, especially to genetic material (DNA), is thought to be a major factor in the development of chronic diseases, aging and age related diseases including cataracts and cancer. There is a well-documented association in humans between oxidative damage and diseases like diabetes, chronic renal failure, hepatitis, colitis, allergic skin disease, arthritis, cancer, atherosclerosis, arteriosclerosis, rheumatoid arthritis, cataract formation, age-related macular degeneration, central-nervous diseases including Parkinson's disease and Alzheimer's disease and asthma. In animals, an association between free radical generation and pathophysiology has been demonstrated in many conditions including:

- Inflammatory skin disease in dogs
- Immune-mediated hemolytic anemia (IMHA) in dogs
- Periodontitis in dogs
- Heat stress in dairy cattle
- Transport stress mortality in beef cattle
- Leishmaniasis in dogs
- Cataracts in poodles
- Gastrointestinal tract (GIT) ischemic injury in horses
- Canine chronic hepatitis
- Senile dementia in dogs
- Chronic inflammatory airway diseases including heaves in horses

Cats are uniquely sensitive to oxidative injury to erythrocytes, and Heinz body formation, as the result of exogenous oxidant exposure as well as endogenous disease processes such as lymphoma, diabetes mellitus, and hyperthyroidism.

Antioxidants (also called free radical scavengers) are therefore the major defense against oxidative stress. They are produced within the body and include enzymatic scavengers such as superoxide dismutase (SOD), catalase, glutathione peroxidase; enzymes such as glutathione (GSH) reductase; hydrophilic radical scavengers such as ascorbate, urate, and glutathione; hydrophobic radical scavengers such as tocopherols, flavonoids and carotenoids; the cellular biochemistry that maintains a reducing environment (eg, glucose-6-phosphate dehydrogenase) and the storage and transport of copper and iron ions in forms that prevents formation of free radicals. In addition to these, antioxidants include minerals (eg, selenium), vitamins (eg, C and E), and phytochemicals such as flavonoids, proanthocyanidins, polyphenols, lignans, and other carotenoids. Most antioxidant compounds in plants are polyphenolic and since most plant parts contain polyphenols, most herbs will have antioxidant activity.

Camellia sinensis

Green tea polyphenols (GTP) decrease lipid peroxidation in skin and protect against lipid peroxidation. GTP also scavenges singlet oxygen. GTP in mice increased antioxidant and glutathione peroxidase, catalase, and quinine reductase in skin, small bowel, liver, and lungs. The combined activities make green tea an effective chemopreventive agent against the initiation, promotion, and progression stages of multistage carcinogenesis.

Polyphenolic compounds (catechins) found in green tea were investigated on bovine and human cartilage cultured with and without reagents known to accelerate cartilage matrix breakdown. Catechins were effective at inhibiting proteoglycan and type II collagen breakdown and it was concluded that some green tea catechins are chondroprotective and that consumption of green tea may be prophylactic for arthritis and may benefit the arthritis patient by reducing inflammation and slowing cartilage breakdown.

Green tea consumption decreased oxidative DNA damage, lipid peroxidation, and free radical generation in smokers. Non-smokers also exhibited a decrease in overall oxidative stress.

Potential veterinary uses include:

- Prophylaxis and treatment of cancer, arthritis, atopy, periodontal disease.
- Prophylaxis in animals living in smoking households

Vitis vinifera

Red wines contain a variety of polyphenolic antioxidants. The total antioxidant activity of wines investigated was well correlated with phenol content and polyphenols are, in vitro, significant antioxidants. Procyanidolic oligomers (OPCs) from pine bark and grape seed demonstrated the strongest free radical scavenging activity when compared with citrus flavinoids and other flavinoids.

Resveratrol, a phytoalexin found in red wine, in fact inhibits the metabolic activation of carcinogens, has antioxidant and anti-inflammatory properties, decreases cell proliferation, and induces apoptosis.

The anticataract activity of a grape seed extract (GSE, which contains 38.5% procyanidins) was investigated in hereditary cataractous rats. The results suggested that procyanidins and their antioxidative metabolites prevented the progression of cataract formation by their antioxidative action. Many proteases participate in various ocular pathologies and no really effective treatments are currently available. Procyanidolic oligomers (PCO) from grape seeds have demonstrated protection against proteolytic attack, for the bovine cornea in vitro.

Semen of different ejaculates collected from breeding rams was mixed with various antioxidants including resveratrol. A significantly higher proportion of motile sperm cells was observed in the treated than in the control samples. The frequency of acrosomal defects was lower in the treated groups than in the control. Antioxidants including resveratrol can improve the effects of ram semen preservation.

Oral administration of bioflavonoid antioxidants (containing grape seed extract) to cats at risk for oxidative stress may have a beneficial effect on their ability to resist oxidative injury to erythrocytes.

Potential veterinary uses include:

- Feline leukemia viral infections, feline lower urinary tract disease (obstructed)
- Bovine corneal disorders, various ocular pathologies including retinopathies, antioxidant support for geriatric animals or those with cardiovascular disorders, photosensitization and prevention of sunburn in depigmented animals, antiinflammatory support, prevention of postoperative edema, sports injury edema, treatment of early cataracts and nuclear sclerosis, systemic mast cell tumor

Crataegus (Hawthorn)

Crataegus contains OPCs, so much of what is known about grape seed extract applies to Crataegus. Hawthorn also contains flavonoids and phenolic acids with antioxidant activity. Hawthorn tincture inhibited the oxidation of LDL and VLDL in diabetic patients and provided a protective effect in atherosclerotic rats. Antioxidant enzyme levels were normalised in the liver, aorta and heart tissue. Crataegus has been shown to increase SOD activity in red blood cells in vivo after oral doses.

Potential veterinary uses: Antioxidant support in cardiovascular disease, oxidative stress, capillary disorders, edema, red blood cell disorders such as autoimmune hemolytic anaemia

Silybum marianum (Milk Thistle)

Silymarin decreases lipid peroxidation in hepatocyte plasma membranes, thereby protecting against many toxins. It also suppresses lipoxygenase, hydrogen peroxide, and superoxide. It increases the levels of glutathione in the liver, intestine and stomach and increases SOD activity in red blood cells and lymphocytes. Silybin reduces oxidative damage to kidney cells in vitro. As an antioxidant, silymarin can protect the pancreas against certain forms of damage. Plasma total antioxidant capacity was significantly increased in volunteers taking 858 mg/day silymarin compared with placebo.

Potential veterinary uses: Hepatitis, nephritis, pancreatitis, cholangiohepatitis, toxic injury to liver, hepatic lipidosis

Curcuma longa (Turmeric)

Curcuma inhibits lipid peroxidation in liver and brain tissue; it inhibits hydrogen peroxide and nitrogen generation from macrophages in vivo; reversed alflatoxin induced liver damage in vivo (presumably via antioxidant action and inhibited iron induced lipid peroxidation in the rat liver. Glutathione peroxidase, SOD and catalase levels were also raised, suggesting curcumin inhibits lipid peroxidation by raising antioxidant enzymes.

Potential veterinary uses: Prevention of cardiovascular disease and cancer; arthritis, asthma, eczema, to improve GIT and liver function, chronic anterior uveitis, adjunct cancer treatment.

Salvia miltiorrhiza (Dan Shen)

Dan Shen is a potent antioxidant with free radical scavenging activity and has been used as antioxidant therapy in heart-lung bypass surgery to reduce myocardial damage and attenuate postoperative vasoactive mediator imbalance. It protects rat hepatocytes against carbon tetrachloride (CCl4)-induced necrosis.

Potential veterinary uses: Impaired peripheral and cerebrovascular circulation, acute and chronic liver disease, promotion of healing of fractures and other injuries, nerve compression, as an adjunct to treatment of lymphoma, autoimmune disease, recovery from cerebrovascular accidents

Vaccinium myrtillus

Phenolic compounds (anthocyanosides) in bilberry inhibit protein and lipid oxidation, bilberry has a particular affinity for the eyes. Anthocyanoside concentration in the fresh fruit is approximately 0.1–0.25%, while concentrated bilberry extracts are usually standardized to 25% anthocyanosides.

Potential veterinary uses: Progressive retinal atrophy (PRA), nuclear sclerosis, capillary fragility, geriatric patients

Schisandra chinensis

Schisandra lignans act as free radical scavengers and inhibit iron-induced lipid peroxidation (including brain cell mitochondria and membranes) and superoxide anion production; they increase SOD and catalase levels in the liver in vivo.

In a randomized, double-blind, cross-over study, 18 healthy horses received a single dose of *Schisandra* concentrate (equivalent to about 50 g of dried berries, containing 1.2% schisandrins) or placebo 30 minutes before a test race. For the race horses, the exercise consisted of an 8-minute race over 5.6 km. The show-jump horses were taken over a 700 m obstacle course with 12 jumps. Treatment with *Schisandra* reduced heart rate and respiratory frequency, increased plasma glucose,and decreased lactate levels in both exercise groups, although the effects were more marked in the race horse group. The *Schisandra*-treated show-jump horses completed the circuit in a shorter time than the controls

In an earlier study involving Thoroughbred horses a single dose of extract equivalent to 192 g of *Schisandra* fruit produced similar results to the above study. The race horses were on average 1.8 seconds faster over 800 m (Ahumada, 1989). It was postulated that *Schisandra* may cause a lower synthesis of lactate in muscles under anaerobic conditions and also stimulate lactate clearance by the liver. Significant reductions in serum levels of GPT, GOT, and creatine kinase was observed in poorly performing horses at days 7 and 14 after oral administration of standardized *Schisandra* extract ($P<0.01–0.05$) compared with baseline values. The sport horses selected for the trial had persistently high enzyme levels. Horses treated with placebo did not experience significant reductions in any enzyme.

Potential veterinary uses: To improve the detoxifying capacity of the liver, acute or chronic liver diseases, including hepatitis; chemical liver damage, poor liver function, preventing and treating oxidative stress in performance animals

Astragalus membranaceus

Astragalus has potent antioxidant activity. It increases red blood cell SOD and reduces lipid peroxide levels. The cardiotonic activity of astragalus may be related to its antioxidant activity. Of 14 Chinese herbs testes against lipid peroxidation in rat heart muscle, Astragalus was found to be one of the most potent.

Potential veterinary uses: Geriatric support, congestive heart failure, early heart failure, chronic infections, immune deficiency, cancer

Ginkgo biloba

Ginkgo biloba extract has significant antioxidant activity due to the flavonoid and terpinoid components. The antioxidant activity is most evident for cardiovascular events such as hemorrhage into tissues, ischemia and also retinal detachment. It also has anti-angiogenesis activity in solid tumors.

Potential veterinary uses: Cognitive dysfunction, cardiomyopathy where hypercoagulability is a concern, bronchitis and asthma, peripheral circulation disorders, central nervous system ischemia (ie, from trauma), hypercoagulation disorders, possibly stress (oxidative or induced by glucocorticoid excess) from chronic illness.

Zingiber officinale

Ginger contains high levels of antioxidants. A study investigated the effects of ginger root extract (GRE) on the viability and production of nitric oxide (NO) and prostaglandin E_2 (PGE_2) by sow osteoarthritic cartilage explants. GRE reduced NO and PGE_2 production by cartilage tissue explants suggesting an important role for GRE as an antiarthritic agent in osteoarthrosis in the sow.

Potential veterinary uses: Adjunct to cancer care and chemotherapy, osteoarthritis, improving circulation in geriatric or nonambulant animals

Table 1. Summary of Prevention of Disease with Antioxidant Herbs

Cancer and prevention of metastases	Turmeric, ginkgo, Green tea, Ginger, Grape seed
Cognitive dysfunction	Ginkgo, Schisandra, OPCs (Hawthorn, grape seed extract)
Cataracts	Ginkgo, bilberry, green tea, grape seed
Cardiovascular disease - including ischemia, retinal detachment	Hawthorn, astragalus, turmeric, dan shen, ginkgo, grape seed, bilberry, ginger
Liver damage	Silybum, Schisandra, green tea
Age-related processes	Green tea, ginkgo, bilberry, ginger, grape seed, any of the antioxidant herbs
Periodontal disease	Green tea

Table 2. Summary of Disease Management with Antioxidant Herbs

Cancer	Turmeric, ginkgo, Green tea, ginger, grape seed
Autoimmune disease	Turmeric
Inflammatory disorders	Turmeric, ginger, grape seed
Liver disease	Schisandra, Silybum, Dan shen
Pesticide poisoning	Schisandra, silybum
Cardiovascular disease	Hawthorn, astragalus, turmeric, dan shen, ginkgo, Grape seed, shisandra, ginger
Eye disease	Bilberry, grape seed
Diabetes	Ginkgo, bilberry
Peridontal disease	Green tea

IMPROVE TREATMENT OUTCOMES WITH VETERINARY ACUPUNCTURE

Deborah M. Mitchell, DVM, MS
Knollwood Hospital for Pets
Schaumburg, IL

Are you familiar with the Covey concept of “sharpening the saw”? It is a parable that addresses the need to periodically assess and update one’s working skills, instead of endlessly plugging along using the same, increasingly less applicable work tools. Whether you are a Covey fan or not, there is no denying that there are more diagnostic tools than the ones you already have – and use daily.

When you dig into your medical bag of tools, can you be confident that you have the right tool for the job at hand? Or are you relying on your comfortable, old, hand-me-down tools? Today we’re going to talk about two terrific tools that you definitely need to think about adding to your medical bag. Both are time-tested, efficient, and safe. Both take time to learn how to use properly, but they can change the way you practice. And, if you learn them, they’ll change the way you think about medicine and the way you approach your patients. In this article, we’ll talk about veterinary acupuncture and in companion articles in this proceedings, about traditional Chinese medical (TCM) diagnostics and herbal medicine, as well as their application to emergency care. TCM concepts pertinent to small animal urinary tract disease and skin disease are discussed in subsequent articles.

Acupuncture is the piercing or stimulation of specific points on the body, typically by means of a very thin, flexible needle. Stimulation of an acupuncture point causes a complex cascade of body responses and the release of various neurochemicals and hormones in the CSF and bloodstream. Acupuncture can be used to diagnose and treat specific patterns of dysfunction and can be used to maintain homeostasis.

LEARNING EFFECTIVE AND SAFE VETERINARY ACUPUNCTURE

There are many possible approaches to learning basic, effective veterinary acupuncture. All will involve approximately one year of your time, during which you can expect—with due diligence—to complete an extended acupuncture course and to master the basics of veterinary acupuncture. It is no more possible to learn good acupuncture skills during a weekend course than it would be to master the basics of small animal orthopedic surgery during the same time frame. You may choose to learn about acupuncture as a sole therapeutic entity, as is taught at one prominent and respected American veterinary acupuncture institute, or as a medical treatment that is just one component of a TCM approach, as is taught by two other extremely reputable institutions, including the original international course for veterinarians which is still considered the ‘gold standard” course. And, having learned acupuncture, you can choose to approach your patients from the traditional western medical approach we've all learned and are comfortable with, or from a TCM approach which may seem rather foreign at first. Once you've decided upon a philosophy and an approach, you will still have to decide whether to integrate acupuncture into your existing practice or to make to move to an entirely different sort of specialty practice.

Some of us may be happy, and satisfied, to learn about techniques that can be comfortably plugged into existing practice: far fewer C-sections or bloat cases, safe alternatives to nonsteroidal anti-inflammatory drug (NSAID) use, fewer cases where we have to admit to the client that there is nothing we can do. Others of us will be more intrigued than intimidated by a medical tradition that is independent of Western medicine, and we may elect to learn more about it. Regardless of our preferred approach, one thing is clear: acupuncture is a discipline that takes time to learn, more time to learn well, and more time still to practice it effectively and painlessly

In his chapter in Veterinary Acupuncture, author and prominent veterinary acupuncturist Dr. Sheldon Altman has this to say about getting started in veterinary acupuncture: "The most important quality in becoming a successful and legitimate veterinary acupuncturist is first of all to aspire to be as good a veterinarian as possible. It is the obligation of the veterinary acupuncturist to be familiar with current conventional techniques of diagnosis and treatment.......The second most important factor in becoming a legitimate acupuncturist is the veterinarian's knowledge of acupuncture....."

WESTERN AND EASTERN APPROACHES TO ACUPUNCTURE

Western (allopathic) veterinary medicine offers a reductionist, mechanistic, linear view of the world. Since Descartes' introduction of analytic, reductive reasoning in the seventeenth century, the focus of modern Western medicine has been to view the body as a machine made up of distinct and separate parts. The body became divided into systems, similar to the parts of an automobile. We still view the heart as a pump, the nervous system as a telephone network or a computer. According to Descartes, each part of the body can be further analyzed and its functions explained. To this day, we are focused on how things work; we all learn the details of innumerable cycles and cascades. In the mid nineteenth century, Louis Pasteur developed the germ theory of disease. While this theory permitted an examination of how epidemics occur (TCM had explored and completely developed this concept several centuries before) and how they can be effectively treated, it further fixed in many minds the concept of cause and effect with respect to disease. We still view symptoms as manifestations of disease, and it is considered a "cure" when we eliminate the symptoms.

We learn about diseases by learning about lists of symptoms. For a great many diseases, we learn standard treatment protocols. We apply these same protocols to many different types of patients, as long as their basic symptoms match the disease we want to treat. We sometimes view patients as a manifestation of their major symptom—"this bloat cow, that cardiac dog"—and we may ignore symptoms that don't fit the picture we are building. We take a problem-oriented history, examine the patient by body system, develop differential diagnoses, test our theories, and arrive at conclusions. We utilize an extended battery of tools, tests, and techniques to establish our diagnoses.

In the past few years, Western veterinary medicine has eagerly jumped upon the “”evidence-based medicine” bandwagon, which our MD counterparts began exploring over a decade ago. We are slowly discovering that many western medical practices, therapies, and treatments near and dear to our hearts hold up quite poorly when subjected to such scrutiny. TCM, by contrast, holds up to such scrutiny remarkably well. Acupuncture can certainly be learned and utilized using either an Eastern or a Western approach. It can be unsettling to learn that more than one approach—in fact wildly divergent approaches—can be used to explain the same phenomenon, and you'll need to decide which approach is for you. It is largely a matter of personal comfort with your existing view of how you and your patients fit into veterinary medicine and the world in general. We’ll review briefly how each system interprets veterinary acupuncture.

WESTERN VETERINARY ACUPUNCTURE THEORY

From a Western perspective, we could say that acupuncture and acupressure can be thought of as a way to influence the function of internal structures by external pressure or needling at pre-defined points. When we utilize acupuncture, we are piercing the acupuncture point in a very precise way, with a specialized needle. When we utilize acupressure, we are applying a broader-based, less precisely located, pressure over the point. Both techniques are time honored and work extremely well.

Externally, acupuncture points can be superficially identified as foci of increased electrical conductivity on the skin. Points can be easily located by instrumentation, and these localizable points correspond exactly to locations identified over 1500 years ago in China. Microscopically, acupuncture points can be identified by their characteristic structure. A published body of work documents their locations and morphology. Visible via electron microscopy, they are an exquisitely complex structure of vessels and nerves that occurs at no other place in the body. When we stimulate an acupuncture point, either by acupressure or acupuncture, we cause a complex cascade of body responses and the release of various neurochemicals and hormones in the cerebrospinal fluid (CSF) and bloodstream. Acupuncture can be used to diagnose and treat specific patterns of dysfunction and also to maintain homeostasis.

Needling or otherwise stimulating a point activates small diameter nerves which travel to the dorsal horn of the spinal cord. From there, they cross to the opposite side of the cord, enter the brainstem, and eventually innervate the hypothalamus and pituitary. These higher centers respond by releasing neurotransmitters including endorphins and serotonin which reduce the perception of pain. In addition, further inputs are dampened in a process known as descending inhibition.

Since acupuncture points are usually reflexively linked to distant sites such as internal organs and other musculoskeletal structures, tissue damage in those distant structures frequently is sensed as pain at the acupuncture point. In addition, the afferent impulse from the damaged structure constricts the venules of the point, leading to a build up of heat and edema. This focal accumulation of heat relative to the surrounding area can be easily perceived in part because of the thin epidermis overlying the point. Swelling is contributed to by the concentration of mast cells typically located at acupuncture points. This triad of symptoms— heat, pain, and swelling—often makes acupuncture points easier to identify. When we needle or apply pressure to the painful and swollen point, a second reflex arc is probably produced that eventually ends back at the inflamed structure after first entering the brain. Within the brain, three different centers are activated, resulting in the release of neurotransmitters that reduce the sensation of pain. In addition, blood flow through the damaged tissue is normalized, resulting in a reduction of edema and exudation and an improvement of microcirculation. The net effect is healing of the damaged tissue and an immediate relief of pain.

These network connections provide not only analgesia but an opportunity for the damaged tissue to heal itself, explaining why acupuncture is regularly curative in disorders that would ordinarily be viewed as requiring more definitive therapy. Numerous studies have demonstrated a favorable effect on hemodynamics and innervation to damaged internal tissues following stimulation of external acupuncture points.

In Western minds, acupuncture is largely viewed as a cause-and effect phenomenon. A great deal has been learned about the structure and physiology of acupuncture points and pathways, and the physiologic effects of acupuncture are well explained by western medicine. What is less understood is the mechanism of action. A number of theories exist; all partially explain why and how acupuncture works. None explains it fully. Current thought holds that these theories are interrelated. It is thought that the degree of involvement of each mechanism depends upon the acupuncture points used relative to the suspected disease process as well as to the acupuncture techniques used.

EASTERN (TCM) VETERINARY ACUPUNCTURE THEORY

Caveat: It is important to realize that most TCM practitioners would view the use of acupuncture alone as incomplete treatment for any given patient. Rather, they would utilize a balanced approach that might include dietary recommendations, exercise or massage, herbal therapy, and acupuncture.

TCM offers a coherent system of thought which is entirely independent of Western medicine. It is a logical and absolutely consistent medical approach that has been evolving for over two thousand years. TCM provides a holistic view of the world in which unbalanced energy patterns contribute to disease and disease contributes to unbalanced energy patterns; there is no cause and effect. Health and disease are viewed as interrelated, dynamic processes and, in an individual, as a microcosm of the world. What happens inside an individual is a reflection of what happens in the world at large.

When evaluating a patient, we recognize the importance of many things, which Western medicine is just beginning to consider relevant: social interactions, air quality, temperature and humidity, season of the year, nutrition, pulse, and tongue appearance. We place a huge emphasis on observing, and talking to, the patient, gathering a careful history, and fully evaluating the patient by using all of our senses. Symptoms are important guides to viewing imbalances, but we recognize that presenting symptoms by themselves don't identify disease. A given symptom may represent many different disease states, and several individuals exhibiting the same set of symptoms may in fact have wildly divergent disease processes going on.

There are no standard protocols, because we recognize that health and disease states are specific to the individual. Our goal is not to quickly eliminate symptoms, because when we eliminate symptoms all at once we lose our ability to understand how the body is responding to our treatment. Rather, our goal is to gently restore balance—symptoms will shift, on their own, in response to restored homeostasis.

Most veterinary acupuncturists find that in order to be more than minimally competent, they need to learn at least a little about TCM. Although the vocabulary and concepts at first glance sound strange to Western ears, they have withstood the test of time, and they do allow us to treat our patients as the individuals they are.

YIN-YANG THEORY

The underlying concept that supports all of TCM is the thought that a part (a symptom, a disease) can be understood only in its relationship to the whole (the patient). Symptoms are sentinels for disease but do not define a disease process. Nor are symptoms isolated entities; they are a part of a generalized body imbalance that can be identified, by careful questioning and examination. This concept of all things being seen as part of a continually cycling whole is called Yin-Yang theory. Yin (pronounced YEEN) and Yang (pronounced YAHNG) are simply labels that describe how anything functions in relation to itself and to the world. Yin is generally described as having attributes of cold, damp, passivity, and darkness. Yang is described as heat, dryness, movement, and brightness. Yin and Yang represent two opposing points of a continual cycle; they are not static. Yin becomes Yang; Yang becomes Yin.

THE FIVE FUNDAMENTAL SUBSTANCES

In TCM, there are five basic body components that are critical to physical and mental balance. These are Qi, Jin-Ye, Blood, Jing, and Shen. They are intimately interrelated and have many corollary organ relationships. The patterns of their imbalances—deficient or excess—and the affected related organs provide highly reliable keys to diagnosis and appropriate treatment. Acupuncture can be used to manipulate the quality of these substances in order to facilitate balance.

THE ORGANS

The TCM system of anatomy is based on functional relationships. Organs are defined by their functions and by their relationship with the Fundamental Substances, with other Organs, and with other parts of the body. There are few parallels between Eastern and Western organ systems. TCM recognizes six Yin and six Yang Organs. Briefly and simply, Yin Organs store, transform, and regulate the Fundamental Substances; Yang Organs actively break down, absorb, transfer, and excrete. Organs are paired in a Yin-Yang relationship. Each paired Organ system has a specific physiologic and psychological function.

- Paired Organs are (Yin Organ listed first):
- Heart/Small Intestine (HT/SI)
- Pericardium/Triple Heater (PC/TH)
- Spleen/Stomach (SP/ST)
- Lung/Large Intestine (LU/LI)
- Kidney/Bladder (KI/BL)
- Liver/Gallbladder (LIV/GB).

MERIDIANS

Meridians are the channels that carry Qi and Blood in a constant cycle throughout the body, allowing these substances to travel to Organ systems and allowing the Organ systems to communicate with each other. There are six main paired Meridians which correspond to the above-mentioned Organ pairs and many other Extra Meridians which may or may not be paired. Imbalance in an Organ can block or slow the spread of Qi through the related Meridian; likewise, damage to a Meridian can affect the related Organs. Acupuncture treatment of points along an affected Meridian can facilitate the movement of Qi to the Organ or Meridian to restore balance. Herbs can also affect specific Meridians and/or Organs, as can other TCM treatments such as exercise and diet.

ACUPUNCTURE TECHNIQUES

There are hundreds of acupuncture points on our animal patients. Precise knowledge of point location, depth, point suitability for the condition or imbalance being treated, and proper needling technique are mandatory before you begin treatment. Acupuncture is usually performed using one of the following techniques:

Acupressure, manual stimulation of specific acupuncture points, is an ancient technique used to stimulate the flow of Qi. It is an excellent technique to relax patients and to relieve pain. Most owners can be taught acupressure techniques for home use, to maintain or extend their pet's response time to traditional acupuncture.

Dry needle acupuncture is an ancient and extremely effective technique in which sterile, preferably disposable acupuncture needles are inserted into specific acupuncture points. Needle length and gauge varies with the patient, specific point, and needle technique. Developing an effective and painless needle technique requires considerable practice and should only be attempted by trained individuals.

Aquapuncture: Acupuncture points can be stimulated by injection of sterile solutions into the point, with a hypodermic needle and syringe. The solution continues to stimulate the point until it is absorbed. Aquapuncture enjoys most use in equine patients where it may be practical to complete treatment very quickly. However, hypodermic needles cause more pain and can cause tissue damage. Experienced veterinary acupuncturists often find that dry needle acupuncture provides superior results to aquapuncture. Still, a growing number of integrative practitioners are finding that good aquapuncture results can be obtained with use of substances such as injectable homotoxicologic remedies.

Electroacupuncture, the electrical stimulation of acupuncture points, is an effective technique for acute and chronic pain states, CVI patients, oncology patients experiencing chemotherapy-related GI side effects, and intervertebral disk disease cases. It is less commonly used for analgesia. Most electrostimulator units are convenient, cost portable and usually battery operated. Effective units allow the operator to vary the amplitude, mode, and frequency of the stimulation.

Moxibustion, or stimulation of an acupuncture point by heat, is an effective treatment for chronic pain, especially in the winter months. Typically, heat is applied at the tip of an inserted acupuncture needle; the heat travels along the needle shaft to the acupuncture point. Moxibustion is highly effective but caution must be taken to avoid burning the pet's skin. The typical odor of the herb used in moxibustion is highly recognizable to many clients and can cause some consternation in a crowded or poorly ventilated hospital. In-room switch-on ceiling ventilation directly to the out-of-doors is advised.

Gold bead implantation: In cases where prolonged treatment of a point is needed, sterile gold wire or beads can be implanted in the acupuncture point(s). Implantation is usually reserved for cases that cannot be treated traditionally (chronic severe seizure disorders; navicular disease). While results can be impressive with this technique, the risks of anesthesia, scar tissue formation, and migration of the beads must be considered.

IMPROVIED TREATMENT OUTCOMES WITH VETERINARY ACUPUNCTURE:

Pain

Hip dysplasia, spondylosis, degenerative joint disease (DJD), and disk disease patients make up the vast majority of my acupuncture patients. These are patients who, if responsive to acupuncture, will require regular treatment for the rest of their lives. Treatment is usually easy, results are predictable, and client satisfaction is exceptionally high. These are very rewarding patients to treat. Many clients become consistent sources of referrals.

Healing of Chronic Wounds

Chronic, non-healing wounds often respond favorably to the use of acupuncture in combination with topical herbal therapy. A substantial body of research documents the efficacy of electroacupuncture in stimulating healing of properly stabilized non-union fractures.

Oncology Patients

Everyone who has not been hiding under a rock for the past decade now knows the Ogilvie mantra: “Don’t let ‘em vomit, don’t let ‘em hurt.” Acupuncture benefits include relief of chemotherapy-induced side effects (GI; leukopenia), reduced pain, and improved immune function, sense of well-being, and remission time.

Immune-Mediated Disease

Acupuncture effects on humoral and cellular immunity have been documented in diseases such as systemic lupus erythematosus (SLE), rheumatoid arthritis (RA), myasthenia, pemphigus, immune-mediated thyroid disease, and asthma.

Dermatologic Patients

Acupuncture releases endogenous corticosteroids (CS), suppresses mast cell degranulation, and increases circulating IgE. Dependence on corticosteroids, antihistamines, and antibiotics can be substantially reduced in most patients. See the article in this proceedings on TCM management of dermatologic disorders for details.

Seizure Patients

Seizuring patients often present with phenobarbital-induced hepatotoxicity and/or an inability to tolerate potassium bromide. Acupuncture can reduce hepatic enzyme levels and resolve GI intolerance of these drugs. It also can be used to reduce the dose of, or number of, medications in polypharmic seizure patients.

Neurologic Patients

Acupuncture is effective in early resolution of neurologic symptoms in CVA patients and is useful adjunctive therapy in the treatment of many myelopathies. Senile geriatric patients who have resumed infantile elimination patterns often respond well to acupuncture.

Renal Disease and Lower Urinary Tract Disease

Acupuncture treatment can improve quality of life for many geriatric patients with chronic renal failure (CRF) by increasing diuresis, limiting proteinuria, controlling nausea, anorexia, and anemia, and improving general attitude. Patients with cystitis, dysuria, and incontinence often respond well to acupuncture. Renal failure associated with cisplatin treatment has responded extremely well to acupuncture. See my notes on TCM management of urinary tract disorders for details.

Hepatic Disease

Patients suffering from hepatitis, fatty liver disease, and liver changes associated with drug administration (CS, phenobarbital, chemotherapeutics) often improve with acupuncture treatment. In addition to resolution of anorexia and related symptoms, hepatic enzyme values often improve dramatically.

Cardiovascular Disease

Acupuncture, when used in conjunction with appropriate herbal and medical therapy, often permits better management of patients with cardiac disease. Faster stabilization of congestive heart failure (CHF) patients is possible and many maintain well on very low doses of appropriate medications. Boxers with hypertrophic cardiomyopathy (HCM) and Dobermans with dilated cardiomyopathy (DCM) often stabilize longer that with traditional Western treatment alone. Specific acupuncture points such as GV26 are associated with profound sympathomimetic effects, making them particularly applicable to emergency use.

Respiratory Disease

Feline asthma, allergic bronchitis, and respiratory diseases secondary to cardiac disease have all been treated successfully with acupuncture. Emergency presentations of respiratory disease often respond particularly well to acupuncture, which can generally be performed at the same time and without hindrance to other life-saving measures. Specific points are discussed in the “”Crashbox” article in this proceedings.

Dystocia

I have performed only two C-sections since learning acupuncture in 1992.

Other applicable conditions (ones with which I have less personal experience) include reproductive disorders, behavioral disorders, and surgical analgesia.

PROFESSIONAL VETERINARY ACUPUNCTURE ORGANIZATIONS

American Academy of Veterinary Acupuncture (AAVA): The best group for gaining an introduction to veterinary acupuncture. Non-certified veterinarians interested in learning about acupuncture can join as associate members. The AAVA has an excellent newsletter, regional CE meetings, and holds an annual meeting, along with many meetings held in the US in conjunction with major allopathic veterinary conferences and the American Holistic Veterinary Medical Association. Membership benefits include membership in IVAS. You can contact the AAVA at: www.aava.org.

International Veterinary Acupuncture Society (IVAS): Chartered in 1974; the international group for veterinary acupuncturists. Irregularly published journal and newsletter, annual meeting with formal proceedings book, location varies around the globe. IVAS’s Web site is www.ivas.org.

CERTIFICATION IN VETERINARY ACUPUNCTURE

IVAS: IVAS provides the longest-established post-graduate education. Their course is offered each year in the US and another location. The course begins each year in fall and ends in the following spring. In addition to four half-week formal seminar sessions, extensive home study is required to successfully complete the exams. Certification follows attendance at all sessions, satisfactory performance on quizzes and practical exams given in sessions, successful completion of final written and practical examinations, many hours spent in preceptorships with other veterinarians certified in veterinary acupuncture, and acceptance of one peer-reviewed case report suitable for publication in the IVAS journal.

Other courses: (All offer approximately 120 hours of instruction):

- CSU: Focus is on Western approach to acupuncture utilizing a strong background in neurophysiology.
- Qi School: Balanced approach in which students may specialize in small or large animal acupuncture.

NEW QUESTIONS, OLD ANSWERS: TRADITIONAL CHINESE VETERINARY MEDICAL DIAGNOSTICS

Deborah M. Mitchell, DVM, MS
Knollwood Hospital for Pets
Schaumburg, IL

Learning even a few basic diagnostic principles of Traditional Chinese Veterinary Medicine (TCVM) will allow you to view your patients as the individuals that they are, with signs unique to them, rather than as category-specific "cases." This, in turn, will allow you to develop treatment plans as individualized as your patients. Your success in treating your patients can expand as rapidly as you allow your diagnostic skills to improve!

The tenets of TCM, which we'll talk about in this article, are easy and intuitive to learn. Some may seem foreign at first glance – tongue and pulse, for instance. I was taught, in vet school, to use pulse-taking to discreetly determine whether euthanasia solution had achieved its intended effect. Tongue evaluation was largely restricted to determining whether a patient was cyanotic. Yet other basic TCM diagnostic techniques are common to those used by any good western practitioner: collecting a good history, conducting a thorough physical examination, and making time for questions the client might have. Even these techniques are much more fully developed in TCM, however.

GENERAL TCM DIAGNOSTICS

In TCM, disease isn't an enemy, and health and disease are not the opposing ends of a linear physiologic continuum. Disease, like aging, is a specific process of life. It results from the interaction of pathogenic factors and the body's vital energy, or Qi. A healthy body's self-regulating systems allow it to acclimate to an ever-changing environment, and a dynamic balance between Yin and Yang promotes very strong vital Qi. If the body has strong vital Qi, it can clear pathogens, restore balance in the event of an internal imbalance, and repair any damage the pathogen or imbalance may have caused. Ideally, it will do so in a dynamic fashion, so that balance is restored and normal body processes proceed harmoniously.

If a pathogen successfully affects the body in a persistent manner (either because the body cannot clear it or the body cannot repair itself, or both), symptoms and signs begin to be apparent. Symptoms are subjective abnormal sensations and thus, in our animal patients, are often more advanced when detected than they would be in us. Signs, or objective displays of symptoms, are more easily detected in our patients. When we observe a specific pattern of symptom that we have seen before and therefore recognize, we generally feel comfortable enough to call that a specific "disease". This allows us to embark upon further diagnostics to confirm our impression, and gives us the confidence to develop a treatment plan and to assess the results of our treatment.

In TCM, we rely largely upon pattern identification as a diagnostic strategy. A pattern refers to the collection of signs representing a given stage of a disease, and it provides the perspective for treatment. Yet we recognize that patterns can be fluid and that as such, our treatment approach must be readily modifiable. Some find it terribly frustrating that treatment in TCM can be so "slippery"; I find it endlessly intriguing and ultimately satisfying to know that there will always be a way to proceed, always a way to provide answers to a worried client, and always a way to bring comfort to my patients.

Western medicine is often viewed as a highly developed and extremely sophisticated medical system. The reality is that those of us trained in this medical system are, at best wonderfully sophisticated generalizers and "lumpers" who – despite an amazing variety of diagnostic tools - often fail when faced with patients whose presenting symptomatology deviate from the normal range of signs and symptoms that we have learned. Try as we might to follow appropriate diagnostics and therapeutics, a given subset of patients simply won't respond. What do we do? Most of us employ more diagnostics, more therapeutics, or we refer the patient for more of the same elsewhere. Interestingly, a similar subset of non-responders emerges each time – just under a different veterinarian's care! And our usual response? We either define a new disease process – often including the word "idiopathic" in the title; or we chronically medicate the patient; or we decide the problem has a psychological basis and we re-refer to another specialist who continues the treatment cycle.

What if we revised our mindset to consider that we have failed the patient rather than insisting that the patient failed the correct treatment? We could begin to consider the possibility that we failed to correctly diagnose the underlying problem by oversimplifying the issues related to that patient's disease.

Here's how to avoid failures in the diagnosis and management of any disease state: examine your patient thoroughly, and listen to what your patient is telling you. Your patient is never wrong. Utilizing traditional TCM examination and diagnostic techniques can greatly expand your ability to succeed instead of fail. I'm not suggesting that you abandon your western examination methods – rather, I suggest that you continue to utilize them while adding a few more simple and quick TCM exam techniques.

The four basic TCM diagnostic tools you need to know about are inspection; auscultation and olfaction; interrogation; and palpation and pulse examination.

Inspection includes evaluating your patient from the moment she enters the exam room. Quickly evaluate gait, bearing, vitality, overall appearance, vocalizations, and then conduct a full medical examination. Use your western tools every time – otoscopes and ophthalmoscopes are meant to be used! A thorough eye exam gives a good opportunity to evaluate the cornea, anterior chamber and iris (related to Liver/LIV); pupil and lens (related to Kidney/KI), conjunctiva and sclera (related to Lung/LU), canthal area (related to Heart/HT), and lids (related to Spleen/SP). Remember that Qi from all the organs rises to the eyes and that the Bladder/BL and Gall Bladder/GB channels originate at the eyes. Check the ears, the external opening of the Kidneys, for any excretions, which are very often diagnostic for internal disorders of excess heat (LIV, GB) or deficiency heat (LIV or KI Yin). Evaluate the nose, the external orifice of the LU and a point of penetration of the Stomach/ST channel, for discharges, dryness, or excess moistness; there are at least 8 distinct differentials for nose issues alone! Evaluate the coat carefully; the hair of the head is related to the health of KI and that of the body is related more to LIV. Qi, Jing, and Blood are also reflected in the coat. Examine the mouth, gums, and teeth, recalling that the mouth is the opening of the SP and that both ST and Large Intestine/LI channels go around the lips while the teeth and gums reflect the health of the KI and ST. Note the mobility of the neck; in addition to giving you a wonderful opportunity to evaluate your patient's chiropractic status if you have this skill, the tone of the neck muscles and vasculature will tell a great deal about the state of the LIV (stiffness, distended/pulsating vessels); the KI and SP (flaccidity); and will help you detect presence of any Qi stagnation or Blood stasis (pain, vascular distension with pulse knotting). Evaluate the thorax and abdomen for shape, symmetry, presence of any masses, and note the respiration – is the patient breathing from the chest or the abdomen? Evaluate the thoracic and lumbar spine, recalling that the GV and BL channels pass along this area while the Dai channel runs circumferentially (like a belt) across the lumbar area. Look for any cold or warm areas along the spine or any points of pain, turgor, or flaccidity, and evaluate their position. Often, these will reflect pathology in a specific organ relative to BL channel points. Or, they may represent an acute (warm) or chronic (cold) chiropractic subluxation. Inspect all the limbs, recalling that disorders related to the internal organs can sometimes be identified through changes in external acupuncture points along the channels on each limb. Note any areas of limb tenseness, spasm, rigidity, trembling, or flaccidity, as the limbs are often areas where evidence of external pathogen influence will be seen (hot/swollen/painful/reduced ROM joints). Carefully evaluate the skin, which reflects LU health and *wei qi* (protective Qi) status. Look for color changes (reflecting heat, Yin or Yang-type jaundice, or KI deficiency); swellings or growths, and note the location of any abnormalities seen. Lastly, evaluate the tongue. While a good, thorough description of what is evaluated in the tongue could go on for weeks and while tongue evaluation and use in TCM diagnostics takes years to master, there are a few very easy and quick to learn points you'll take home today. We'll approach evaluating the tongue as we do the neurologic exam: from general to specific.

- Is the tongue overall normal or abnormal looking?
- Is it appropriate for the patient's size and breed?
- Is there anything about the tongue that looks especially weird? Where and what?
- Is the color a nice, healthy pink, or is it another color?
- Is the tongue a normal shape or is it shaped oddly (thin, thick, short, long, asymmetric?)
- Is there any kind of a coating on the tongue? If so, what color and where is it?
- Is there any marking, growth, or crack on the tongue? If so, where?

Now, what does it mean? All of the organs, the Jing, the Qi, and the Blood physiologically nourish the tongue in some way, and thus the tongue will reflect pathology in any of these areas. We'll illustrate this with a PowerPoint "tongue review and quiz".

Next comes auscultation and olfaction of your patient. Listening to vocalizations, to the heart and lungs, and paying careful attention to odors is important because all are related to the patient's physiologic status and potential pathologic changes. It is possible - through inspection, auscultation, and olfaction - to detect organ and general body pathology far before laboratory changes will ever be noted. Even emotional pathology can be detected this way – be sure to attend Dr. Boudreaux's lecture on this topic for more information. In addition to the usual cardiac and respiratory evaluations we are all accustomed to, auscultation can tell us a great deal about the state of the Shen, about body excesses or deficiencies, and about specific Organ pathologies, most notably those of the HT, KI, and LU when we auscult the chest. Ausculting the abdomen can reveal pathology of the ST, SP, LI, SI, and LIV when we hear borborygmi, belching, and flatulence. Olfaction is another very detailed science in TCM. Fan of five element theory know about normal and abnormal odors associated with each element and, by extension, with each organ. Assessing specifics of the odors associated with flatulence, sweat, stools, urine, vomit, and any secretions from any orifice is a time-honored TCM technique that can reveal fascinating details about a patient's health.

Interrogation allows us to subjectively obtain details about a patient's main symptoms as well as any complicating symptoms. I try to always use the classic TCM "ten questions" as part of obtaining a full history. It is always interesting to check how many of these questions you might already be asking as part of a complete patient evaluation. I found, in fulfilling the most current American Animal Hospital Association requirements for medical record-keeping, that acceptable examination forms require that one document at least some version of all ten questions, just as Chinese physicians have been doing since at least the Ming Dynasty (1368-1644, approximate time of publication of the *Shi Wen* (Ten Questions/Ten Aspects to Interrogate in Verse). There are many versions of the ten questions; here is a simple one:

- Is the patient more hot or more cold? Where does the pet choose to rest? Sunshine-seeker?

- How much does the patient sweat? (Species dependent, you may be assessing skin/nose/footpads)
- Is there any pain? If so, where? When? How often? How long? Fixed or moving?
- Is there any vertigo, dizziness, or are there any other abnormal sensations?? Head tilt/staggers?
- What are the BM & urine like right now? What are they usually like? When did they change?
- How is the appetite? What does this pet eat? What else? What else? What else? Supplements?
- What are this pet's drinking habits? How much? How often? Actually drinking or just hanging out at the water bowl? What is the owner using as a measuring device for food and water?
- Energy status? Stamina? Is either one better or worse at certain times of day or night?
- Sleep habits? Where? When? How long? Dreams? Restless?
- Reproductive status? Cycling normally? Interested in breeding? Over/under-interested?

Obviously, there are other questions you will want to ask within the context of an office visit. However, these ten questions form the framework for making important decisions about diagnosis and treatment. As with tongue diagnosis, we can liken the "ten questions" to conducting a good neurologic exam – once you get the exam pattern down and repeat it conscientiously, it soon becomes second nature. Rather than formally sitting down and asking all ten at once, you can easily incorporate them into directed, focused conversation with the client as you are examining your patient.

Lastly, we'll consider pulse examination and palpation. In TCM, these are considered a single activity, but with two distinct methods. Pulse examination, like tongue diagnosis, is both an art and a science. Pulse-taking has been utilized in TCM since BC, times; it was formalized as a science with publication of the *Mai Jing* (Pulse Classic) during the Western Jin Dynasty (circa 300 AD). Its publication precedes the first monograph on tongue diagnosis, the *Ao Shi Shang Han Jin Jing Lu* (Ao's records of the Golden Mirror of Febrile Diseases), Yuan Dynasty, by nearly a thousand years. In our animal patients, we differ from the human patient custom of taking both radial artery pulses as well as pulses in an upper (head), middle (hand) and lower position (foot); we utilize just the femoral arteries instead. Some practitioners evaluate all three pulse positions at all three levels but most commonly, one position is used and is assessed at all three levels. Depending on the text utilized, one can draw various relationships between the pulse positions and the internal organs. Normally, pulses will vary with species, age, sex, utility of the patient, season, and other factors such as emotional status, food intake, and medications. However, pulses are highly patient-specific and thus changes over time in the same patient have great significance. While up to 37 different qualities can be assessed in the pulse, even the novice can quickly evaluate the following:

- Is the strength appropriate for the patient?
- Is the speed appropriate for the patient?
- Can the pulse be felt in all 3 depths (with light, medium, and heavy pressure over the artery?)
- Is the pulse regular/reflective of normal sinus arrhythmia?
- Is what you feel symmetrical?
- Do you feel anything weird when you feel the pulse?

Palpation, like pulse-taking is also an art and a science and fortunately, most veterinarians are quite skilled at palpation. In TCM, there are four aspects to palpation: light touch with the fingers or palm, "feeling" with slight pressure using the entire hand, pressing or firm pressure using the hand, and tapping or percussive activity to detect fluid accumulation or Qi stagnation. The entire body is palpated. Acupressure points are also palpated for heat, tenderness, stagnation, or accumulation. Diagnostic points such as association and alarm points are thought to be especially significant and reflective of specific organ dysfunction if they are found to be reactive or abnormal upon palpation. They can also be used as an indicator of treatment success, since they will normalize with appropriate treatment.

Once the full exam is completed, the TCM practitioner uses the collected data to develop an impression of pattern identification. Some patients "fit" a specific pattern exactly, just as we sometimes see in western medicine. Commonly, however, a patient (especially the chronically and multiply diseased, polypharmic, geriatric patients we so often see in veterinary medicine), are a mishmash of presenting signs. We may be able to get no further that establishing the answers to four basic questions:

- Is the location of the disease attacking the exterior (skin, muscles, hair, channels, vessel) or the interior (Organs, Qi, Blood, bone, Marrow) of the body?
- Is the disease a hot or a cold disease?
- Is the patient deficient or excess?
- Is the overall classification Yin (cold, interior, deficient) or Yang (hot, exterior, excess)?

If we can get this far, we are well along in establishing a diagnosis or at least how to proceed. But if we can't get this far, we can use other TCM diagnostic systems that will still allow us to proceed. For example, if we can identify a specific external or internal causative pathogenic factor, we can use pattern differentiation specific to these factors. If we can identify a specific TCM Organ as being affected, we can utilize organ-specific pattern differentiation. If we can only decide that the disease is a hot or a cold-type disease, we can utilize diagnostic systems specific to each type. If we can get no further than determining a general region of the body that is affected, we can use Jiao-specific differentiation, choosing treatment options specific to the upper Jiao (HT, LU), middle Jiao (ST, SP, LIV), or lower Jiao (LIV, KI, SI, LI).

It is worth noting that an astute Western-focused practitioner could elect to bypass any further TCM diagnostics once the full exam is completed, and successfully revert to a Western final diagnostic and therapeutic plan. Simply by virtue of having collected a far more detailed history and evaluation of the patient using the simple TCM tools discussed, any practitioner can effectively integrate this information into established treatment protocols and expect to achieve improved treatment outcomes.

As long as one takes a careful history; examines the patient thoroughly, completing all parts of a good TCM and western exam; asks any necessary questions to clarify the case; and then looks for a pattern that fits the majority of the significant clinical signs, it is really quite difficult for any practitioner to go wrong.

SAVE THAT DYING PATIENT! THE TCM CRASHBOX

Deborah M. Mitchell, DVM, MS
Knollwood Hospital for Pets
Schaumburg, IL

There are abundant veterinary medical resources to suggest what should be in your crashbox, and most of them adequately prepare the practitioner for a successful resolution for the majority of medical emergencies. In this article, we'll discuss some simple additions that can improve your success rate dramatically—without requiring more space. In my small animal practice, the full contents of my crashbox fit into a five drawer rolling cart. The drawers are alphabetized without regard to whether the contents are allopathic or alternative: for example, acupuncture needles are nestled next to injectable aminophylline, and Yunnan Paiyao, an herbal medication for speedy control of even severe bleeding, shares space with venostomy sets.

ACUPUNCTURE NEEDLES

These belong in everyone's crash cart, for use in emergency treatment points. An advantage to the use of acupuncture in emergency medicine is that acupuncture needles can generally be placed while other supportive, more traditional emergency care is being provided without detriment to the patient. Emergency treatment points include points on virtually every body meridian. With rare exception, "point prescriptions," or combinations of points, are generally the most effective way to treat emergency patients, Locations for all points mentioned can be found in any good veterinary acupuncture text.

Use of acupuncture needles requires some degree of practice, because they do not have a cutting edge such as is present on a hypodermic needle. Effective sizes of needles for emergency use are usually narrow gauge and short. Two sizes, 0.22x13 mm and 0.20x25 mm, will generally be adequate. In the absence of acupuncture needles, I would not hesitate to use a 25-gauge hypodermic needle. However, the cutting edge of hypodermic needles represents an additional patient risk, especially if many are used. Acupuncture needles, by contrast, will rarely produce bleeding. Acupuncture needles are single use and require disposal in a suitable sharps container.

Suggested points and point combinations for a variety of common emergency presentations are listed below.

- **Abortion or parturition induction:** LI4; SP; SP6; CV2, 3,4,5; and KI11,12,13,14 stimulation for 5-10 minutes, using strong manual stimulation, will stimulate abortion or induction of parturition. I have not done a single cesarean section since I began using these points over 10 years ago.
- **Acute asthma:** LU9 and CV22 calm and regulate acute asthma. A special point not on any meridian, Ding Chuan, is also very useful, especially in feline asthma. It is located midway between the GV and inner BL meridian, at the level of the caudal end of C7. Especially in panicky felines, the superficial nature of these points makes laser use more effective than dry needling.
- **Acute vomition:** PC6 is exceptionally effective in relieving even extreme nausea and vomiting associated with hypovolemia, whether due to infection, chemo, motion sickness, or postoperative complications.
- **Acute diarrhea with hypovolemia:** ST36 combined with ST25 is very effective; in exceptionally weak patients, combine with CV8 and use moxa.
- **Cardiovascular collapse:** GV26 stimulation induces a profound sympathomimetic response sufficient to induce resumption of normal cardiac rhythm in a flat-lined patient. KI1and HT9 must generally be treated for several hours afterwards, at judicious intervals, to maintain a stabilized rate and rhythm.
- **Tachyarrhythmias:** PC5,6; BL15; ST9; BL1,2; ST1 all slow HR.
- **Ventricular arrhythmias:** PC6 increases the fibrillation threshold and in rabbits, is equally as effective as lidocaine. Sympathetic-induced arrhythmias are controlled well by simultaneous stimulation of PC6 and ST36
- **Dilated cardiomyopathy (DCM):** PC6 increases stroke volume and CO, increases LV outflow, and decreases pulmonary capillary wedge pressure. PC7 and HT7 improve systolic function in general.
- **Hypertrophic cardiomyopathy (HCM):** Traditional Chinese medical journals report the use of HT8 in improving LV outflow, stroke volume and CO. Use of PC6 worsened the same patients.
- **"Heartworm treatment crisis":** Needling of HT7; LI4; LIV8; LI11; and ST36 can help stabilize patients.
- **Equine colic:** ST2; BL21; BL25; ST36; CV1; Bai Hui.

ACUPRESSURE POINTS

Acupressure involves finger pressure over specific acupuncture points. Acupressure points can also be stimulated by use of needles; however, the following points respond especially well to digital pressure. The following points are so important and so useful, there is no excuse for any practitioner to not know them and not to teach them to their staff:

1. GV 26: Resuscitation point; profound sympathomimetic effect; Restores normal cardiac rhythm. This point is so well known that even cardiologists teach it in cardiac resuscitation lectures.
2. ST 36: Master point for abdomen; Direct innervation to upper GI; Indicated for vomiting, diarrhea, bloat, and colic.
3. BL 60: "Aspirin point"; potent pain relieving point anywhere in the body; contraindicated in pregnancy.

4. SP 6: Immune function; Master point for pelvic organs; Tonifies Qi, Blood, and Yin; Indicated for GI and genital disorders, allergy and immune disorders, fatigue and weakness.
5. LI 11: General heat-clearing (skin or bladder infections); cools Blood, clears Heat & Damp; stops itch; enhances immune function.
6. KI1: Very strong resuscitation point, generally used in combination with GV26. Helps "ground" the dying patient back to earth.
7. PC6: For relief of nausea to extreme vomition, especially in situations involving shock.

HERBAL MEDICINE

There are three herbal medications eminently suitable for use in emergency situations: Yunnan Paiyao, Ren Shen, and Zi Cao. Both Yunnan Paiyao and Ren Shen are available in formulations that are easy to administer (orally or rectally) even to a critical patient. Zi Cao is a topical ointment, which is very useful in the emergency management of extensive skin injuries, including burns and trauma.

Yunnan Paiyao is a patent herbal medication. The precise formula is a closely guarded secret of the Chinese government. It first came to Western attention during the Vietnamese War, when it was found in the possession of enemy soldiers who utilized it as part of their medical field kits. It is an exceptionally effective hemostatic when used either topically or orally. There is extensive scientific documentation to confirm its positive hemostatic effects. Decreased bleeding time and shortened in vitro and in vivo clotting times have been documented in rats, rabbits, cattle, and ponies. It may be administered before and/or during a hemorrhagic crisis and is commonly used for any of the following: internal and external bleeding tumors, sheared toenails, surgical bleeds, epistaxis, coagulation disorders (i.e. thrombocytopenia), gastrointestinal hemorrhage, abdominal trauma, aural hematomas, avian bumblefoot, OHEs in estrus, and oral/dental procedures. Doses for Yunnan Paiyao are as follows:

- Dogs: <15 kg = 1 capsule PO BID; 15–30 kg = 2 capsules PO BID; >30 kg = 2 capsules PO TID.
- Cat: 1/2 capsule PO BID
- Horse: 1 bottle or 16 capsules PO TID
- Bird: 1 capsule dissolved in water PO SID.

Ren Shen, or Chinese Ginseng, is a potent tonifier of the TCM Spleen and Lung and of Yuan Qi, the original source of all of the Qi (energy) of the body. It revives "collapsed Yuan Qi," a TCM diagnosis characterized by shallow respirations, shortness of breath, cold extremities, rapid weak heartbeat, and a feeble or nonpalpable pulse—a condition akin to what we would call hypovolemic end-stage shock. Extensive medical studies have documented Ren Shen's positive ionotropic effect on the hearts of dogs, cats, and rabbits. It is mildly vasoconstrictive and slightly increases BP. For shocky patients, tiny and frequent doses (0.5–1 g, hourly) are suggested. Known Ren Shen herb–drug interactions include MAO inhibitors, insulin, glipizide, glyburide, and tolbutamide. Of particular interest to some readers may be Ren Shen's documented amelioration of the impairment effects of ethanol on learning and memory processes.

Zi Cao Ointment is a proprietary formulation developed by a collaboration between an OMD and a DVM. It is exceptionally effective in treating trauma injuries, extensive degloving injuries, skin lesions, burns, and non-healing or poorly healing wounds. Zi Cao possesses antibiotic and antifungal properties. From a TCM perspective, it drains damp and heat, and moves Blood. Because it speeds granulation so effectively, it should NOT be used for puncture wounds.

HOMOTOXICOLOGY USE WITH ACUPUNCTURE

At least three homotoxicologic remedies have specific utility for emergency room situations: Traumeel, Hepar Compositum P, and Lymphomyosot. I typically inject these into appropriate acupuncture points or utilize a 'circle the dragon" aquapuncture technique.

Traumeel is the quintessential remedy for any injury characterized by tissue bruising, crushing, and edema. It is available in tablets, oral drops, oral vials, in a topical cream and a gel, in an ear drop (useful for ruptured eardrums) and in an injectable form. The common acupuncture technique of "circle the dragon" is very effective when used with injectable Traumeel. In this technique, tiny boluses of Traumeel are injected circumferentially to the lesion.

Hepeel, available in tablets and vials, is effective in bloat, colic, and anorexia cases, as well as in any case of severe unremitting diarrhea or nonspecific severe abdominal pain. It is available as an injectable and as an oral tablet.

Lymphomyosot is useful whenever there is extensive generalized tissue damage. Available as a tablet, oral drop, oral vial, injectable solution, and topical gel, it reduces edema markedly and speeds healing.

WEB SOURCES FOR REFERENCED CRASHCART ADDITIONS

- Homotoxicology products are available through Heel, Inc. at www.HeelUSA.com
- Herbal products are available through many sources; I utilize www.atimetohealherbs.com. Acupuncture needles are available from a number of sources. I utilize Hwa-To or Serin needles from Lhasa Oriental Medical Supply, at www.LhasaOMS.com.

EDUCATIONAL RESOURCES FOR THOSE NEW TO ACUPUNCTURE

AAVA: American Academy of Veterinary Acupuncture: The best group for those interested in learning about veterinary acupuncture. Non-acupuncture certified members are welcome to join as associate members. The AAVA has an excellent newsletter and a highly informative annual meeting that is rapidly growing in popularity and attendance. They also sponsor tracks at most major veterinary meetings across the United

States as well as at the AHVMA meeting. AAVA membership benefits include membership in IVAS, the International Veterinary Acupuncture Society. AAVA can be contacted at: www.aava.org

AHVMA: American Holistic Veterinary Medical Association. Founded in 1981, this American group includes veterinarians, RVTs, and veterinary staff interested in a wide range of holistic modalities, including acupuncture. They have an interesting quarterly journal and an absolutely superb annual meeting. This multi-tracked meeting includes presentations from a wide range of allied holistic groups, including the AAVA and groups affiliated with veterinary botanical medicine, homeopathy, and veterinary chiropractic. The AHVMA has recently added a specific technician track and an introductory day track to the annual meeting. This group is warmly welcoming to new members and to first time attendees. I make it a point to never miss this meeting! They can be contacted at: www.ahvma.org

TEXTS THAT SHOW AND DESCRIBE LOCATIONS OF AACUPUNCTURE POINTS ESPECIALLY WELL FOR BEGINNERS

1. Schwartz C. Four Paws, Five Directions: A Guide to Chinese Medicine for Cats and Dogs. Berkeley, CA: Celestial Arts Publishing, 1996.
2. Zidonas N, Soderberg M. Canine Acupressure: A Treatment Workbook. Parker, CO: Parker Printing, 1995.

TCM PERSPECTIVES ON URINARY TRACT DISEASES: PHYSIOLOGY, DIAGNOSIS, AND TREATMENT

Deborah M. Mitchell, DVM, MS
Knollwood Hospital for Pets
Schaumburg, IL

Are there extremely detailed, astonishingly precise, and very effective ways to evaluate and treat urinary issues besides the ones you already know about? Thankfully, there are – because we all face the frustration of doing exactly the right thing for refractory urinary tract cases with patients who stubbornly refuse to respond! One such approach is the diagnostic and therapeutic intervention opportunities found in Traditional Chinese Medicine (TCM). In 1992, I realized – while listening to a lecture on the diagnosis and treatment of urinary diseases in the International Veterinary Acupuncture Society (IVAS) course one afternoon– that what I was listening to represented a unique and better way to evaluate and treat the refractory urinary issues I faced in my patients every day. This immediately sparked a life-long interest in the principles of traditional Chinese medicine (TCM). Learning TCM allowed me to view the constellation of signs we call "cystitis" and "incontinence" and "renal failure" through another lens – one much more specific than the one I was used to using.

The tenets of TCM that allowed me to make this quantum leap in patient care are easy and intuitive to learn. They encourage us to view our patients as the complete individuals they are rather than as "cases." Viewing them as such will allow you (with the appropriate training) to develop treatment plans as individualized as your patients. Your success in treating these difficult patients will then expand exponentially. Are there additional holistic modalities you could choose to use, probably with good success? Yes! Once you open your eyes to the possibility of diagnostic and treatment options besides the ones you already know, you'll be amazed by the richness of what is available to you. In this article and the companion articles in this proceedings, we'll be emphasizing those within my areas of expertise and those in which I have seen remarkable success when all other treatment approaches have failed.

To a holistic or integrative practitioner, what is limiting about how we view cases from a Western perspective? In Western medicine, when we observe a specific pattern of symptoms that we have seen before and therefore recognize, we generally feel comfortable enough to call that a specific "disease." This allows us to embark upon further diagnostics to confirm our impression, and gives us the confidence to develop a treatment plan and to assess the results of our treatment. Western medicine is often viewed as a highly developed and extremely sophisticated medical system – and it does generally work well, until we are faced with patients whose presenting symptomatology deviate from the normal range of signs and symptoms that we have learned. When our treatment protocols fail, what do many of us do? We term the disease idiopathic or assign the failure to the patient, rather than place the failure where it belongs – with us, in most cases.

Despite this, Western medicine is still the predominant therapeutic mode used today, here in the United States. Given that this is the "gold standard" we are held to as veterinary practitioners, it goes without saying that an appropriate integrative medical workup always includes a thorough, all-systems Western medical examination, use of all appropriate Western diagnostics, and may include some elements of traditional allopathic Western medical therapy. Thus, in discussing urinary disease, we will assume that you have collected and documented a thorough history, that you have a good understanding of the exact nature and duration of the problem, appropriately obtained a sterile urine sample, thoroughly evaluated it, run a urine MIC and appropriate bloods, evaluated any crystals or calculi if obtainable, and radiographed, ultrasounded, and biopsied your patient as appropriate. Additionally, an appropriate Western medical follow-up protocol, on a schedule determined by the patient's condition, should always be established and documented in the medical records.

TCM DIAGNOSTICS REVIEW

In the previous articles, we covered the basic principles of a thorough TCM examination. As a brief review, we'll use them to consider, from a TCM viewpoint, how to evaluate and treat the conditions of "cystitis," "incontinence," and "renal failure."

Recall that in TCM, disease is not an enemy, and health and disease are not the opposing ends of a linear physiologic continuum. Disease, like aging, is a specific process of life, resulting from the interaction of pathogenic factors with the body's vital energy, or Qi. Healthy bodies have a better self-regulating mechanism, better adaptability to an ever-changing environment, and a very strong vital Qi. Thus, pathogen-clearing and internal damage repair proceeds harmoniously. Pathogens that affect the body in a persistent manner (either because the body cannot clear it or the body cannot repair itself or both) allow symptoms, or subjective abnormal sensations, and signs, or objective displays of symptoms, to become apparent.

In TCM, we rely largely upon pattern identification as a diagnostic strategy. A pattern refers to the collection of signs representing a given stage of a disease, and it provides the perspective for treatment. Patients vary over time and thus patterns can be fluid; this means that our treatment approach must be readily modifiable.

Utilizing traditional TCM examination and diagnostic techniques can greatly expand your ability to succeed instead of fail. Examine your patient thoroughly, and listen to what your patient is telling you. Your patient is never wrong. Do not abandon your Western examination methods – rather, continue to utilize them while adding a few simple and quick TCM exam techniques.

Recall that the four basic TCM diagnostic tools you need to know about are inspection, auscultation and olfaction, interrogation, and palpation and pulse examination. Details of each technique are included in my TCM Medical Diagnostics lecture.

Inspection includes evaluating your patient from the moment she enters the exam room. Quickly evaluate gait, bearing, vitality, overall appearance, vocalizations, then conduct a full medical examination. The ophthalmologic exam, specifically with respect to the urinary system, provides clues to the health of KI, BL, and GB. The ears, the external opening of the KI are often diagnostic for internal disorders of excess heat (Liver/LIV, GB) or deficiency heat (LIV or KI Yin). Recall that the coat is related to the health of KI and to LI. Examine the mouth, gums, and teeth, recalling that the teeth and gums reflect the health of the KI and ST. The mobility, tone, and vasculature of the neck will tell a great deal about the state of the LIV (stiffness, distended/pulsating vessels); the KI and SP (flaccidity); and will help you detect presence of any Qi stagnation or Blood stasis (pain, vascular distension with pulse knotting). Evaluate the thoracic and lumbar spine, recalling that the GV and BL channels pass along this area while the Dai channel runs circumferentially, like a belt, across the lumbar area. Look for any cold or warm areas along the spine or any points of pain, turgor, or flaccidity. Often, these will reflect pathology in a specific organ relative to BL channel points. Inspect all the limbs, recalling that disorders related to the internal organs can sometimes be identified through changes in external acupuncture points along the channels on each limb. Recall that from a TCM perspective, lower back and knee pain is often viewed as a KI issue. Carefully evaluate the skin; look for color changes which may reflect KI deficiency. Lastly, evaluate the tongue. All of the organs, the Jing, the Qi, and the Blood physiologically nourish the tongue in some way, and thus the tongue will reflect pathology in any of these areas.

TCM auscultation and olfaction of your patient - listening to vocalizations, to the heart and lungs, and paying careful attention to odors - is important because all are related to the patient's physiologic status and potential pathologic changes In addition to the usual cardiac and respiratory evaluations we are all accustomed to, auscultation can tell us a great deal about the state of the Shen, about body excesses or deficiencies, and about specific Organ pathologies, most notably those of the HT, KI, and LU. Olfaction is another very detailed science in TCM, as it once was in Western medicine. Even in Western medicine today, most of us can easily recognize – and know the significance of - the odor of uremic breath.

Interrogation allows us to subjectively obtain details about a patient's main symptoms as well as any complicating symptoms. Try to always use the classic TCM "ten questions" as part of obtaining a full history. Here is a simple version:

- Is the patient more hot or more cold? Where does the pet choose to rest? Sunshine-seeker?
- How much does the patient sweat? (Species dependent)
- Is there any pain? If so, where? When? How often? How long? Fixed or moving?
- Is there any vertigo, dizziness, or other abnormal sensations? Head tilt/staggers?
- What are the BM & urine like right now? What are they usually like? When did they change?
- How is the appetite? What does this pet eat? What else? What else? Supplements?
- What are this pet's drinking habits? How much? How often? Actually drinking or just hanging out at the water bowl? What is the owner using as a measuring device for food and water?
- Energy status? Stamina? Is either one better or worse at certain times of day or night?
- Sleep habits? Where? When? How long? Dreams? Restless?
- Reproductive status? Cycling normally? Interested in breeding? Over/under-interested?

As with tongue diagnosis, we can liken the "ten questions" to conducting a good neurologic exam – once you get the exam pattern down and repeat it conscientiously, it soon becomes second nature.

Lastly, complete your pulse examination and palpation. In TCM, these are considered a single activity, but with two distinct methods. Pulse examination, like tongue diagnosis, is both an art and a science. In our animal patients, we utilize the femoral artery pulse. Normally, pulses will vary with species, age, sex, and other factors such as emotional status, food intake, and medications. However, pulses are highly patient-specific and thus changes over time in the same patient have great significance. It is relatively easy to quickly evaluate the following:

- Is the strength appropriate for the patient?
- Is the speed appropriate for the patient?
- Can the pulse be felt in all 3 depths (with light, medium, and heavy pressure) over the artery?
- Is the pulse regular/reflective of normal sinus arrhythmia?
- Is what you feel symmetrical?
- Do you feel anything weird when you feel the pulse?

Palpation, like pulse taking is also an art and a science and fortunately, most veterinarians are quite skilled at palpation. In TCM, we palpate the entire body four times: first, with light touch with the fingers or palm, then with slight pressure using the entire hand, next with firm pressure using the hand, and finally by use of tapping or percussive activity to detect fluid accumulation or Qi stagnation.

Acupressure points are also palpated for heat, tenderness, stagnation, or accumulation. Diagnostic points such as association and alarm points are thought to be especially significant and reflective of specific organ dysfunction if they are found to be reactive or abnormal upon palpation. They can also be used as an indicator of treatment success, since they will normalize with appropriate treatment. Once the full exam is completed, the TCM practitioner uses the collected data to develop an impression of pattern identification. Occasionally, patients "fit" a specific pattern exactly, just as we sometimes see in Western medicine. Commonly, however, a patient (especially the chronically and multiply diseased, polypharmic, geriatric patients we so often see in veterinary medicine), is a mishmash of presenting signs. We may be able to get no further than establishing the answers to four basic questions:

- Is the location of the disease attacking the exterior (skin, muscles, hair, channels, vessel) or the interior (Organs, Qi, Blood, bone, Marrow) of the body?
- Is the disease a hot or a cold disease?
- Is the patient deficient or excess?
- Is the overall classification Yin (cold, interior, deficient) or Yang (hot, exterior, excess)?

If we can get this far, we are well along in establishing a diagnosis or at least how to proceed. As long as one takes a careful history; examines the patient thoroughly, completing all parts of a good TCM and Western exam; asks any necessary questions to clarify the case; and then looks for a pattern that fits the majority of the significant clinical signs, it is really quite difficult to go wrong.

TCM URINARY PHYSIOLOGY

We all recognize the organs of the urinary system in western medicine, and we conveniently divide them into upper and lower urinary tract organs and related disease processes. The western system is simple, easy to understand, and straightforward to utilize. But it just doesn't work for many of our patients. Try as we might to follow appropriate diagnostics and therapeutics, a given subset of patients simply don't respond.

What if we revised our mindset to consider that we have failed the patient rather than insisting that the patient failed the correct treatment? We could begin to consider the possibility that we failed to correctly diagnose the underlying problem by oversimplifying the issues related to urinary tract disease. And if we begin to look at urinary tract disease from a TCM perspective, we'd see that there is scarcely a body organ that *couldn't* be involved in diseases of this system, either directly or as a paired organ with another organ that is actively involved. Urinary tract disease is truly a "three-Jiao", full-body disease. Let's look at potential organ issues alone:

Suspect #1: Spleen. The SP role in fluid metabolism, and separation of fluids into "pure" fluids that go to the LU and "impure" fluids that go through further digestive processes in the SI and LI before being shunted in one form to the BL makes this TCM organ a possible culprit. If the SP is somehow impeded or disrupted in its role in fluid and food metabolism, normal movement of fluids will be impaired, causing Dampness or Phlegm accumulation. This can be associated with a variety of urinary health challenges, including pain, dribbling, incontinence issues, and even renal failure.

Suspect #2: Lung: It is said that the LU oversees the body's 'water passages," dispersing fluids to the skin and to the KI. When the lungs take in the Qi of the air, it must be "grasped" by the KI in order for both organs to function properly. If the LU is weak, descending LU Qi won't properly carry fluids down to the BL via the San Jiao/SJ. If the KI is weak, it can't control its orifices properly. Issues such as incontinence and poor urine concentration can result.

Suspect #3: San Jiao: The SJ is the body's highway system for fluids and other substances. When the SJ is disrupted in its role in water movement throughout the body, dampness will occur. Long-term dampness accumulation thickens dampness into Phlegm. Think of a compost pile – over time, it may heat up and even combust. Dampness and heat can be associated with pain, burning, abnormal urine patterns, and even urolithiasis formation.

Suspect #4: Intestines: The SI and LI, with "power" coming from KI Yang, separates the fluids coming to it from the ST, and decides what portion of the fluids goes to the colon and what goes to the BL. If impeded in this function, fluids will not move properly to the BL, and BL fluids can become turbid and thick, with eventual heat accumulation..

Suspect #5: Heart: Normally, the HT and KI enjoy a mutually beneficial relationship in which descending HT Yang warms the KI, allowing it to "steam" some of its Yin back up to the HT. This "steam" serves to cool and restrain the HT so it can act in a discerning manner to control the entire body in its relationship with the exterior world as well as with the interior of the body. If HT becomes overheated, its Yang does not descend, the KI become too cool, and incontinence and/or Shen disturbance can result. A hot HT can also cause vascular disruption, with hematuria as an end result.

Suspect #6: Bladder: The BL stores and excretes urine as we understand it to occur in western medicine, saving needed water for the body in the process. The BL also transforms some of the body fluids into Qi, which then helps to control the volume of fluid leaving the body. The BL carries out this transformative process with the help of other water and fluid-transforming Organs: SJ, LU, KI, and SI. When impeded in this function, the urine can become scanty, thick, and hot; or, polyuria with isosthenuria could result.

Suspect #7: Kidney: The KI role in urinary tract disease is far broader than how we understand it to be in western medicine. While adequate urine concentration in TCM is known to be a function of proper KI function, the role of the TCM KI is much more extensive. KI Yang provides the power to separate fluids in SI and LI, supports the Qi transformation of the BL, provides power to "steam" some of its Yin fluids back up to the HT to cool it and to the LU to moisten it, and powers the SP Yang functions of transformation and transportation. The KI also governs the lower orifices, ensuring continence. If the KI fails in any of these functions, a wide range of urinary disorders result.

"CYSTITIS"

Classic signs and symptoms of cystitis as we understand it in the western sense – stranguria, hematuria, bactiuria, pyuria, pollakiuria, urgency, and a thick bladder wall upon palpation - are readily apparent in most of our patients. If we broaden our understanding of cystitis to include the organ systems just discussed, a number of mental "clicks" happen. It becomes apparent that we very probably miss a wonderful opportunity to effectively diagnose and treat a wide range of health challenges before they manifest as a painful cystitis. Realization dawns that we definitely miss treating both overt cystitis and more subtle manifestations such as feline interstitial cystitis most effectively when we fail to address the underlying causative factors. A clear understanding that antibiotics are seldom the best answer develops. An understanding of the obvious link between chronic cystitis and diseases such as TCC emerges. And, we begin to realize that all those frustrating cases of overt cystitis symptoms with sterile urine have a recognized pathology which is easily treatable. Yet - if we smugly elect to treat cystitis manifestations with herbs instead of antibiotics without addressing the underlying causes, are we really doing more of a service to our patients than the veterinarian who prescribed amoxicillin without performing any diagnostics and called it a day?

What we currently understand as cystitis would, in TCM, be viewed simply as a downward movement of damp and heat to the lower Jiao and then to the BL, causing painful, frequent, and urgent urination with odorous yellow urine accompanied by a burning sensation. (Other causes of TCM cystitis exist, but we'll go with what you know). Several causes could be identified for this damp-heat movement. Regardless of cause, the damp-heat need not affect only the bladder. If it moved to other area organs instead, it could manifest as urgent, odorous, hot diarrhea accompanied by anal burning and possibly the passage of mucus or blood (LI); or as an odorous, thick, itchy vaginal discharge; or as a preputial discharge; or as a metritis or an orchitis. And in fact, similar seat-of-the-pants herbal therapies could be effectively employed for all of these conditions.

If we established a goal of addressing the underlying causes for the syndrome we call cystitis, we'd have to first look at acute onsets of damp-heat in the BL. Four or more forms, depending on source, can be identified.

1. *Heat Lin or Re Lin disorder:* Re Lin is associated with acute classic cystitis signs plus dribbling, a red tongue, a rapid pulse and, if not treated quickly by draining the damp and clearing the heat, can result in chronic inflammation. The urine is often very turbid and this form can be very painful. The appropriate classic formula is Ba Zheng Wan, and this is my preferred treatment, with possibly up to 10% Yan Hu Suo (Corydalin) added if pain is substantial, or up to 10% Fu Ling if dampness predominates. Other formulas that have been advocated are Ba-zheng Powder (Xie, hardly a change from the classic formula), or San Ren Tang and Si Miao San (Marsden). Appropriate acupuncture strategies to clear the heat and rain the damp are those advocated by Marsden (SP 9, LI 11, He-Sea points; BL 25, empirical; BL 27, BL She point) and Limehouse (BL 22,28; CV 3,12; SP 6,9). Any acupuncture text will list other points to consider.
2. **Stagnation Lin or Qi Lin disorder:** Qi Lin represents LIV Qi stagnation, which often occurs in association with stress (I see it in agility and show dogs as well as in many cats maintained in isolated or very cat-unfriendly environments), or in conjunction with LIV Blood deficiency (carb-loaded pets, for example). Wood type animal personalities are commonly affected. The stagnancy creates more symptoms of abdominal tenseness and irritability and less damp symptoms than seen in other forms of Lin disorders. The tongue is often lavender to purple, pulses are more wiry. Herbal strategies to calm the LIV, clear the heat, and move the Qi include Wu Yao Tang, Si Miao San*, or Long Dan Xie Gan Tang. (If there is a lot of LIV heat). Appropriate acupuncture points include those advocated by Limehouse (PC 6, ST 30, LIV 3,5,6,8, CV3,5) and Marsden (BL 18, LIV-Shu; BL 27, BL Shu; LIV 8, He-Sea point; SP 6, LJ Qi mover; ST 37, Sea of Blood).
3. Heart Fire: HT fire usually represents an Upper Jiao heat excess; multiple causalities exist. Regardless of the cause; when the HT is too hot, it affects not only the Shen, Blood, and nearby structures such as LU, but organs with which it has a close association, such as KI and its paired organ, SI. Marsden has made the observation that both HT and SI are organs of discernment; the HT discerns to engage appropriately with the external world, ruling how the body reacts to the external, and the SI discerns to engage appropriately with its internal world of separating turbid from clear. When either function fails, normal discernment fails. The organism as a whole becomes flighty, anxious, and easily agitated, and the SI fails to separate appropriately, resulting in less fluid being passed to BL. The HT-SI association also gives us another important diagnostic and prognostic clue that the HT needs treatment, not just the BL: affected animals, usually cats, often will resolve symptomatically and then, later, begin exhibiting inappropriate urination behavior. Untreated, they will also usually relapse with overt cystitis signs, with or without bactiuria. HT Fire is a frequent cause of owner give-ups and unnecessary euthanasia in feline patients. The urine is not only scanty; it heats up and actually feels hot when collected. The tongue is red with a redder tip (why?), the pulse is quite rapid, and other cystitis signs are as previously described; hematuria usually predominates. Herbal strategies to relieve both clinical signs and the HT Fire, include LDXGT, SMS, and Dao Chi San (Guide Out the Red Powder), which specifically conducts heat out of the HT channel via the SI. This formula is effective for both

excess and deficiency types of heat. Appropriate acupuncture points include classic points for cystitis as well as points to calm the Shen, including PC6, the HT and PC association points, GV 20 to descend the Yang, and ST 39, lower He-Sea of SI.

4. **Deficiency Fire:** Debilitated, geriatric patients often suffer from deficient Blood, Yin, or both. When Yin, the body's fluid nature, is deficient, Yang is relatively excess. This causes a relative heat condition, not truly excess in nature, but "hot" all the same. Just as one can get burned by holding a hand over both a low and a high gas flame on the stove, deficiency Fire can dry up the body's fluids, including the urine. The urine becomes thick, scanty, hot, and often cloudy. The condition is often not painful, and the BL may not be thick upon palpation; the body is reduced in its ability to respond. The tongue is red, dry, thin and possibly small, pulses are rapid and weak and/or thin; and the patient generally appears thin and weak, and possibly quite jittery or agitated. Many startle easily or are quite vocal but with a soft voice. Many present with concomitant CRF. Treatment choices must be focused on nourishing the Yin and gently clearing heat. Appropriate herbal formulas are Zhi Bai Di Huang Wan or Liu Wei Di Huang Wan. The former is a variation on the latter, with two herbs added to make it much more specific for clearing vigorous Fire. ZBDHW is my first choice, as few of these patients present in an early enough stage for the latter to be very useful. Marsden's acupuncture prescriptions for fulfilling the stated therapeutic goals include the KI Fire and source points (KI 2,3); BL 23, the KI association point; SP 6, intersecting point of the 3 leg Yin channels, and locally, CV 3.

An important reality check is the realization that many of these acute heat, damp-heat, and Fire patients are quite difficult to needle. Treating an angry, very painful, or very anxious and flighty patient via needling can be a real morning waker-upper. Instead, I will commonly go straight to herbs, or, since I practice integratively, will employ another pain-relieving strategy. Homotoxicology offers wonderful benefits to acute and chronic cystitis patients and, with the use of autosanguis preparations either orally or injected into just one or two acupuncture point with a 30-gauge needle, provides rapid relief of pain and inflammation. The role of chiropractic subluxations should not be ignored; inappropriate sympathetic or parasympathetic stimulation of the bladder or to an organ involved in proper water metabolism, secondary to a subluxation, is a frequently neglected cause of recurrent acute cystitis. Other therapies with documentable efficacy include ozone delivery to the lower Jiao via rectal or vaginal insufflation; QGM or other infrasonic therapy; joint support products such as Arthriease and Cosequin; injectable NSAIDs, such as meloxicam; and non-narcotic pain relievers, such as tramadol.

Chronic causes for cystitis-type syndromes generally represent inadequate treatment of an acute form of cystitis, such as Re Lin or Qi Lin. These can transform into Xue Lin disorder or secondary Blood stasis. Once Blood stasis develops movement of Qi, fluids and (obviously) Blood slows, nutrition to the BL becomes inadequate, toxins cannot be adequately removed, and entanglements of Qi, Blood, and Phlegm can develop. The bladder wall appears thick and engorged to necrotic-looking; in very severe forms of Xue Lin, tumors may develop. Severe interstitial cystitis is one form of Xue Lin; transitional cell carcinoma is another. The tongue is generally red with a yellow coat; the pulse is rapid; the bladder is extremely thick, painful, and friable; hematuria is prominent. In Xue Lin, an important treatment goal is to get the Blood moving; yet if entanglement is present, we must clear this first. Blood cannot move effectively against an obstruction, and forcing it to do so will worsen the patient and cause excruciating pain. This is one form of cystitis where I would turn to homotoxicology before going to herbal therapy, because I have found the matrix-clearing benefits of appropriate homotox remedies to be a better first-treatment step. Once the matrix – the framework through which the static build-up will have to pass – is clear, I will then turn to appropriate TCM herbal remedies. An appropriate herbal formula would be the lower Jiao-specific variant of Xue Fu Zhu Yu Tang (Drive out Stasis in the Mansion of Blood Decoction), which treats dysfunctions with the commonality of Blood stasis. This is Shao Fu Zhu Yu Tang (Drive Out Stasis in the Lower Abdomen Decoction), which is specific for Blood stasis disorders of the reproductive system, the lower back, and the lower abdomen, with or without palpable masses. I often add Yan Hu Suo for its Blood invigorating and stasis-removing (profound analgesic, anti-inflammatory, muscle relaxing, and pain-relieving) effects. For those who don't keep single herbs in stock, good effect can be achieved by adding a second formula that is Yan Hu Suo based Two very nice formulas are Evergreen's Corydalin formula and Dr. Zhao's Corydalis Compound. Evergreen's Herbal Analgesic capsules, a Dr. Richard Tan formula, also work very well for this and any other situation in which substantial pain is present.

There are also several different forms of cystitis-like syndromes recognized in TCM for which western medicine has no name. These are Shi Lin, Gao Lin, and Lao Lin.

1. **Shi Lin:** Sometimes called Stone Lin, this form is characterized by classic cystitis signs, plus crystalluria that can progress to stone formation with resultant urinary obstruction. The tongue is red with a yellow coat, which may be thick and sticky, and the pulse is rapid and wiry. Crystals and stones represent a more extreme form of dampness accumulation, with transformation into Phlegm and eventually into a more solid form. Appropriate treatment seeks to clear Heat, drain damp, and open the water passages so that the stones or crystals can be expelled. An excellent formula is Allen and Boudreaux's proprietary Stone Qi Formula. I have seen this formula resolve

crystalluria rapidly (MAP crystalluria responds much faster than calcium oxylate crystalluria; the makers claim to have seen MAP stones dissolve, but I have not seen this happen, preferring to take seriously affected patients to surgery before they obstruct). Acupuncture points suitable for BL damp-heat conditions would certainly be appropriate, plus BL 63 to remove obstructions from the BL channel, and BL 39 with KI 2, to remove obstructions from BL and free the water passages.

2. **Gao Lin:** Also called Turbid Lin or Cloudy Lin, cystitis of this type exhibits lots of thick, turbid urine, with mucus or clumps of pale to white debris in the urine. Microscopically, these clumps have appeared amorphous when I have looked at them. In the excess type of this pattern, the urine may grow organisms when cultured; in the deficiency form, it is usually sterile. Excess patients have a damp-heat type tongue and pulse and exhibit similar damp-heat signs. Deficient patients usually appear tired, thin, show a pale tongue with or without a coat and a weak pulse, and may have substantial lower back pain. Any good damp-heat formula we have discussed would be appropriate for excess patients. Deficient patients are often treated like Lao Lin patients (below) or with a specific and somewhat difficult to find formula, Gao Lin Tang (Cloudy-Painful Urine Decoction). Acupuncture protocols are similar to those for damp heat (excess form) and Lao Lin (deficiency form).
3. **Lao Lin:** Also called Fatigue Lin or Deficiency Lin, representing chronic disease with a KI Yang deficiency. When Yang is deficient, the patient is cold, weak, and shows more signs of dribbling than with other forms of cystitis syndromes. All signs are worse after exertion. The tongue is pale and sometimes flabby, and the pulse is weak. Treatment goals are to tonify the Qi and KI, raise the Yang, and warm the body. An excellent formula is Bu Zhong Yi Qi Tang (Tonify the Middle and Ascend the Qi Decoction), the classic Qi tonic formula for raising and strengthening the Yang. Acupuncture protocols might include the use of moxa over points such as GV 4 to strengthen KI's Fire of the Gate of Vitality.

"INCONTINENCE"

Incontinence is frustrating to treat because western medicine has such a poor understanding of the causative factors. It is truly a crapshoot with respect to deciding upon appropriate therapy, even according to the experts in the field. TCM recognizes many syndromes, and no two reference sources agree exactly how to differentiate incontinence from enuresis; some do not differentiate them at all. For reasons of time constraint, we'll discuss the top four that IVAS presents in their course clinical lectures, as they encompass many of the types others differentiate individually while introducing some that may be more specific to our animal patients: obstruction of the Dai Mai channel, KI deficiency, HT-KI disconnect syndrome, and urgency from damp heat accumulation syndromes.

1. **Dai Mai obstruction:** Picture this channel as a belt that is too tight, constricting what is under it, and obstructing the flow on either side of it. When stasis occurs in this or any other channel, flow of Qi and Blood is obstructed. Specific to the Dai Mai, KI Jing also "leaks", as does urine. This syndrome can also be associated with pain, weakness, or paresis of the lower back and hind limbs. Regulating the Dai Mai with appropriate acupuncture technique (GB 41, master point, SJ 5, coupling point, and GB 26-28, local points; after Marsden) facilitates a response that can be surprisingly quick. Marsden's suggested formula is Xiao Chai Hu Tang (Lesser Bupleurum Decoction), classically a formula that harmonizes "half interior, half exterior" or lesser Yang/Shaoyang disorders, to speed their resolution. I have had good success with Neuro Plus, an Evergreen specialty formula developed by Drs. Chen and Tan, plus electroacupuncture above and below Dai Mai.
2. **KI deficiency:** Deficiencies of any KI vital substance will cause dysfunction and inability to control the urine. We've already discussed syndromes associated with deficiencies of KI Yin; here we'll consider KI Yang deficiency. In addition to the signs discussed under Lao Lin syndrome, incontinence-specific KI Yang deficiency is associated with a need for frequent urination at night (why?) and feelings of exhaustion and dizziness (why dizziness?). Geriatric pets may present with symptoms of cognitive disorder more than dizziness, which is hard to assess in our patients. The treatment goals and protocols discussed under Lao Lin syndrome are appropriate here, too. If the deficiency is associated with a great deal of lumbar and hind limb pain, I will add either Qi Bao Mei Ran Dan* or Du Huo Ji Sheng Tang* – both will effectively improve comfort, warm the lower back and hind limbs, and improve Blood and Qi flow to deficient areas. Yan Hu Suo* is another consideration, for reasons previously discussed. Jin Gui Shen Qi Wan (Golden Cabinet Kidney Qi Pill) and Tu Si Zi Wan (Cuscuta Seed Pill) are effective. The former works well so long as there is not a tremendous discrepancy between KI Yin and Yang, since it both nourishes Yin and tonifies Yang. The latter is excellent for those patients who are severely deficient to the point of being alarmingly frail and constantly dripping urine (source Qi can no longer fill out the skin and flesh or distribute the Blood and Qi well).
3. **HT-KI disconnect:** This is an extremely interesting syndrome similar, in some ways, to the mutual relationship between HT and SI. Here, however, the relationship is between the HT and KI – the two rulers, if you will, of the most essential aspects of body physiology. When the KI and HT fail to support each other, the HT does not warm the KI and the KI does not send up its Yin to cool the HT. The HT Yang flares into HT Fire, and the KI becomes too damp, resulting in incontinence. Treatment protocols center upon acupuncture to facilitate descending the

HT Yang, and use of formulas that stabilize the KI. Jin Suo Gu Jing Wan (Lock the Essence Pill) works well in my hands. Others prefer Sang Piao Xiao San (Mantis Egg-Case Powder).

4. Urgency from damp-heat accumulation syndromes is another important cause of incontinence, and is easily treated using any of the damp-heat formulas already discussed for cystitis.

However, I am frequently referred cases of incontinence treatment failure that were treated absolutely appropriately from a TCM perspective. Why did these cases fail to respond? Many of them involved very obvious chiropractic subluxations, and the patient's incontinence resolved completely with appropriate chiropractic intervention. It is squirmingly uncomfortable to be the recipient of questions such as "why did my Doctors mess around for three years with first PPE and then imipramine and then DES and then herbs, when you fixed the problem by adjusting her back once?". Please, always remember to radiograph the lower lumbar area in any case of refractory incontinence, and if in doubt about the presence of a subluxation, consider a referral to a certified veterinary chiropractor.

If no subluxations are present, you are certain that there are no other mitigating factors, and the case appears to be chronic-damp heat, homotoxicologic intervention may be most useful. Consider oral or autosanguis preparations of (as is phase-appropriate) Gelsemium Homaccord*, Solidago compositum, Ubichinon compositum, and Plantago Homaccord, using appropriate points.

"RENAL FAILURE"

Renal failure is viewed as having both acute and chronic manifestations in western medicine, with vastly differing presenting signs, symptomatology, and prognoses. TCM views renal failure as a chronic condition, albeit a treatable condition. Many causes exist, but the main ones center upon SP deficiency, KI Yin deficiency, and KI Yang deficiency.

1. **SP deficiency:** This more reflects renal insufficiency than renal failure; most SP deficient patients with KI manifestations appear reasonably well. They are isosthenuric, but remain well hydrated, generally mildly polyuric and polydypsic, and their bloods show only mild elevations in BUN and creatinine. However, they are patients who are walking a thin line, because their KI essence is not able to properly support KI Yin and Yang – and without this, there is poor interaction between the two to "spark" the production of KI Qi. Treatment goals are to tonify the SP and ST so that these Organs remain strong and able to resist invasions of cold and damp that can affect the KI and related organs of water metabolism, and to promote normalization of SP transportation and transformation processes so that normal KI function is supported. Tongue, pulse, and appropriate treatment strategies have been discussed.
2. **KI Yin deficiency:** Untreated, mild KI Yin deficiency will eventually progress to HT Fire and gradual "top dry, bottom wet" disconnect. The upper portions of the body, under the influence of a too-dry and hot HT, "heat up", cause agitation, nocturnal restlessness, increased thirst, a dry coat, weight loss, and general feelings of heat and a desire to select cool surfaces on which to rest. At the same time, the KI Yang cools and sinks, causing polyuria and dampness-obstructive symptoms in the lower Jiao, lumbar area, and hind legs. The patient is weak, painful, and often constipated with a red dry tongue, a rapid pulse, and a feeble appearance that can be masked by agitated activity. Treatment goals are to tonify Yin, cool the HT, and descend HT Yang to warm the KI. Treatment protocols appropriate for deficiency Fire are appropriate here. If mental agitation is severe, calming formulas such as Tian Wan Bu Xian Dan (Emperor of Heaven Pill to Tonify Heart), or Evergreen's Calm ES are useful add-ons. I would not use Calm ES alone, however. While both formulas have strong Shen-calming effects, Calm ES, does not possess the slight Yin-tonifying qualities of TWBXD. If constipation is severe, use Run Chang Wan as adjunctive care.
3. **KI Yang deficiency:** If the KI Yang is weak, the same scenario as above occurs. This time, Yang deficiency signs predominate, with a more static tongue, a weak and deep pulse, and more dampness signs. The end result, of course, will be the same without treatment – Yin and Yang will increasingly separate, and the patient will die. Appropriate treatment goals and protocols are as discussed, with more effort to tonify the KI (BL 23, KI 3, GV 4). The best herbal protocol for patients with this stage of dysfunction is, fortunately, the pleasant tasting tonic formula, Ba Wei Di Huang Wan. Another good choice is Jin Gui Shen Qi Wan.

TCM APPROACH TO DERMATOLOGIC DISORDERS

Deborah M. Mitchell, DVM, MS
Knollwood Hospital for Pets
Schaumburg, IL

If you are reading this article, perhaps you have a creeping realization there is something incomplete with your current approach to common skin conditions such as atopic dermatitis. How do you respond when you see patients with a seasonal allergy that responds to symptomatic treatment but reoccurs every year, usually worsens over time, and eventually starts occurring during non-seasonal times? Many times, owners of such pets insist that their pets are healthy – aside from their skin issues. Yet is not progressive failure to respond to appropriate therapy a suggestion of illness? Years ago, I decided that it was – and that I was just prolonging and worsening the underlying condition by limiting my treatment approach to relieving immediate symptoms.

Western approaches to the treatment of skin disorders excel in treating acute symptoms of skin disease. Antihistamines and steroids work well to relieve acute episodic symptoms, and they work fast. Very few integrative or holistic practitioners are able to relieve acute skin disorders as quickly. Yet allopathic approaches work less well when patients have seasonal disease or underlying causes for their disease. In these cases, success must be measured by more than immediate symptom relief – it must address the cause of the symptoms – and this is where integrative medicine shines!

Successful integrative treatment of skin disorders first requires retraining owners to realistic treatment expectations. Why is this case? Most of the cases that integrative practitioners see have been treated traditionally until response ceases, at which point the patient is generally transferred to a veterinary dermatologist's care. The dermatologist then treats the same patient until response ceases, at which point the patient may be transferred to an integrative or holistic practitioner. In my practice area – the Chicago metropolitan area – the second largest referral source to me is from a large regional dermatology specialty center. These are challenging patients to treat and response certainly does not come as quickly as when the patient received the first steroidal or antibiotic treatment from their primary care veterinarian. However, the owner's expectations may be that response will be as fast as when the patient first developed the skin disease. It is often difficult for clients to wait the 3 to 6 months that may be required to return the patient to a semi- balanced state of health. With a discussed understanding of the reality of the time frame needed to achieve a probable response in the face of long-term unsuccessful past treatments, owner's expectations generally become more realistic.

We all face the frustration of doing exactly the right thing for refractory derm cases with patients who stubbornly refuse to respond. Fortunately, there are a variety of established, medically documented, and very effective ways to evaluate and treat dermatologic issues besides the ones you already know about. In this article, we'll talk about a specific modality that you can use to improve your success with difficult cases: Traditional Chinese Herbal Medicine. Learning the basic principles we'll discuss today will allow you to view your difficult skin cases through a new set of lenses – ones much more specific than the one most of us learned, refined, and still use. Once you learn to view your patients as the individuals that they are, with signs unique to them, that will allow you (with the appropriate training) to develop treatment plans as individualized as your patients. Your success in treating these difficult patients will then expand exponentially.

TCM DIAGNOSTICS

Dermatologic disorders have been recognized as early as the Zhou dynasty (1100–221 BC), when it was noted that some skin disorders were seasonal in nature. They have been formally described as early as early as the 14th century, much earlier than Western medicine had an understanding of the pathologic causes of skin disorders. While dermatologic disorders were not evaluated by laboratory testing or skin scraping or by definition of the cause, successful treatment protocols were described for many types of skin disorders. Formal dermatology textbooks – in the western sense - were first written in the 1960s.

Traditional Chinese medicine (TCM) offers a distinct advantage over Western medicine in its treatment of many cases of skin disease, in that it focuses on treatment of the cause rather than merely relief of the clinical signs. As we've discussed, according to TCM one must look at the whole body in order to treat skin disease. One must complete a thorough examination and history before deciding on a treatment protocol. The ten questions, discussed in an earlier article, must be thoroughly reviewed. In completing the history, the season, location, and description of the lesions are most important. This information will help to determine the chronological order and depth of the disease process.

TCM, like many systems of alternative medicine, recognizes that the root of many cases of skin diseases is an inappropriate diet. As has been amply documented by numerous veterinary nutrition experts, many processed pet food diets are inappropriate relative to the known dietary requirements of carnivores. From a TCM perspective, the chief culprits in processed pet foods are high carbohydrate content, low moisture content and inappropriate ingredient selection relative to the energetic needs of the patient in question. Skin diseases caused by such inappropriate diets fall into two general TCM diagnostic categories we'll discuss: blood deficiency and dampness accumulation. Dogs tend to fall into the blood deficiency category and cats into the dampness category, although both imbalances are commonly found in both species. Most severe cases of skin diseases, if left untreated, progress to the more chronic TCM diagnosis of Blood Heat. This is the stage at which patients are commonly presented for euthanasia if their underlying disease state cannot be resolved. Given the TCM perspective of the importance of diet, it is scarcely surprising that diet is used as a therapeutic tool in the management of skin disease, along with appropriate herbal therapy and acupuncture where appropriate. A fourth common skin TCM presentation is not related to diet much at all – it is more a manifestation of a seasonal weather factor: wind. Wind represents invasion of an External Pathogen Factor (EPF) into the body, where it acts much like it does externally. We might characterize Wind as something that comes and goes, moves frequently, and varies in intensity. Skin lesions associated with Wind Invasion behave similarly.

TCM Diagnostic Differentiators

We'll discuss more specifically how to recognize and treat the conditions of Blood Deficiency, Damp Heat, Wind Invasion, and Blood Heat in detail, after reviewing some common skin presentations and how they "fit" into a TCM diagnostic framework. From a TCM perspective, we can differentiate skin disorders using the primary diagnostic modalities of tongue and pulse, as well as by characteristics of the symptoms, as follows:

Pulse Characteristics

Rapid and forceful: Heat or Damp Heat; Thin: Yin deficiency, and/or Blood deficiency; Weak: Blood deficiency and/or Qi deficiency; Wiry: Stagnation, pain.

Tongue Characteristics

Pale: Blood deficiency; Red: Heat; Swollen: Dampness; White coat: Dampness; Red with thick yellow coating: Damp Heat.

Itching

Red skin with rash: Heat; Extremely itchy with odor: Damp Heat; Itching with dry, small dander: Blood deficiency; Itching with moistness, ventral aspect: Dampness; Itching which moves around the body: Wind.

Location and type of Lesions

Inguinal: Liver; Nasal: Lung; Lips: Spleen, Stomach; Pustules: Damp Heat; Vesicles: Dampness; Nodules & cysts: Qi or Blood stagnation, phlegm, damp.

TCM CATEGORIZATION OF SKIN DISEASE

Blood Deficiency patients that are presented for evaluation often represent those patients with exceptionally dedicated owners. Why? Because Blood deficiency signs are often somewhat subtle, low grade, and very localized, with lesions that sometimes have substantially regressed by the time a worried owner has secured an appointment! Recall that deficiency implies a weakened response; so these patients show little heat, little itching, feel and look reasonably well. They often respond very well to the triad of antibiotics, corticosteroids, and fatty acid supplementation, but given their underlying deficiency status, their symptoms will recur time and time again if the deficiency is not addressed. In the absence of lesions, how might one recognize a Blood deficiency patient? Recall that Blood deficiency specifically implies poor peripheral circulation, in this case, to the skin. Hence, these patients will have dry, thin, "crepe paper" skin, a poor hair coat which often becomes most noticeable after a close grooming or shaving of a specific area of the body, a fine powdery dander, and a low grade itch. Think of geriatric Miniature Poodles as the "poster children" for dermal Blood deficiency manifestations! In addition to these dermal manifestations, patients may also exhibit KCS and musculoskeletal symptoms. Because Blood deficiency can affect the Shen, these patients may also show mild to marked degrees of obnoxious behavior: stealing or guarding food or toys, timidity, excessive barking, and "attack and flee" nipping behavior. Blood deficiency pulses will be thin and wiry, and the tongue will be pale, thin, and with little or no coating. Once appropriate herbal therapy and acupuncture have been initiated, and the patient has improved, long term consideration must be given to correction of the deficiency, by means of adjusting the diet, maintaining an adequate exercise program, and use of digestive support. The exemplar formulas for Blood deficiency is Si Wu Tang.

Wind Invasion patients typically present much more acutely with much more obvious signs that, once they develop, can persist for extended periods of time. Rashes and other eruptive lesions are typical, as is the involvement of other body systems. Wind Invasion patients, for example may present with both multiple hot spots that appeared "overnight," and acute vomiting, diarrhea, or neck and back pain. Wind lesions can vary, depending on what other EPF they are associated with. Wind-Damp lesions will be wet or greasy and possibly swollen or edematous; intact vesicles or papules are characteristic. Wind-Heat lesions will be more likely to be dry, crusty or with peeling epithelial collarettes, and the patient will be more pruritic when the skin is warm – these are the patients who often worsen after a professional grooming.

Tongue signs in Wind Invasion patients are highly variable, and more dependent upon the presence of other factors besides Wind, such as internal or external heat and/or dampness. In a pure early Wind Invasion, the pulse would be expected to be superficial; however, pulse is also heavily influenced by the presence of other EPFs or internal factors. Because Wind Invasion patients often have an underlying deficient condition which allowed the EPF to enter the body, they, too may require long-term attention to resolution of any underlying disorder. Look to Blood deficiency signs to often emerge after resolution of the Wind Invasion is achieved. . The exemplar formulas for Wind Invasion include Xiao Feng San and Si Wu Xiao Feng Yin.

Damp Heat patients are the ones that make everyone want to reach for their entire pharmacy at once! As their name implies, they are "hot and wet" in a most unpleasant way – these patients often have a strong, offensive odor noticeable as soon as they enter the clinic, thick caseous exudates from any affected body part, and oozing hot lesions. They smell and feel greasy even after a fresh bath, and are often obese. The "poster child" for Damp Heat? The American Cocker Spaniel with chronic otitis externa, lip fold pyoderma, pododermatitis, greasy seborrhea, axillary and inguinal moist pyoderma, and anal gland sacculitis. Another classic presentation is generalized demodecosis. Other Damp-Heat clues include frequent bouts of acute cystitis, flatulence, very odorous and noisy diarrhea, chronically elevated liver enzymes, conjunctivitis, and a unpredictably bad temper. The tongue is generally red to purple, wet, and swollen. Pulses are slippery to wiry, depending on whether the Heat or the Dampness predominates and the rate is normal to fast. Exemplar formulas for Damp heat include Long Dan Xie Gan Tang and Si Miao San.

Blood heat completes our quartet of common TCM dermatologic syndromes. Dr. Steve Marsden calls this syndrome the "point of convergence" of virtually all longstanding cases of skin disease. Heat of any kind, from any cause, can manifest as Blood Heat if it is present and untreated long enough. Untreated Blood deficiency, Damp Heat, and external Heat manifesting as an EPF can be root causes. Iatrogenic external Heat causes include deliberate insertion of a pathogen, as can occur with over-vaccination in an ill patient, or over-vigorous treatment of a deep pyoderma or abscess. The absolute characteristic of Blood Heat is intense and persistent itching, to the extent that affected patients frequently and severely traumatize themselves. The skin may appear hemorrhagic and may lack normal integrity. These patients often feel very hot; they are literally unable to cool themselves by normal circulatory processes because their Blood volume is reduced as the Blood heats and dries. As heat follows its natural inclination and rises to the Upper Jiao, the Heart and Shen often become quite disturbed, leading to agitation during the day and altered sleep patterns at night. The pulse is highly variable but usually rapid with elements of inappropriate flow: wiry, choppy, or knotted. The tongue varies from red to brown, depending upon the degree of heat present. The exemplar formula for Blood Heat is Qing Ying Tang.

TCM THERAPEUTICS – HERBAL OPTIONS

Antibiotic and corticosteroid therapies are no less useful to the integrative practitioner than they are to those who practice allopathically. From a TCM perspective, we can certainly exploit known TCM characteristics of such pharmaceuticals to benefit our patients. For example, corticosteroids are both very cooling and quite moistening. Thus, they will especially benefit those patients with hot, dry, skin conditions ranging from Wind Invasion all the way to Blood Heat. However, as overly dry patients improve and their skin rehydrates, corticosteroids can become too Damp producing over time and for Damp-Heat patients, they may actually worsen the skin condition with even short-term use. Severely Damp patients may become "cushingoid" much faster than would typically be expected.

Antibiotics, from a TCM perspective, tend to be both cooling and drying. Thus, they are often excellent short-term choices for Damp-Heat patients, but could seriously impact Wind or Blood deficiency patients, unless concomitant herbal or other supportive therapy is used to correct the underlying dryness. In patients with underlying Spleen deficiencies, characterized as we've discussed yesterday, antibiotic use can be associated with mild to severe GI symptoms unless appropriate Spleen support formulas are utilized.

Herbal therapy is exceptionally effective for acute dermatologic cases whenever traditional therapy is either inappropriate or has been rejected by the client. Such therapy is very often focused on the immediate health challenge and is often short-term, if no underlying excesses or deficiencies are present. Some practitioners elect to proceed in a somewhat allopathic fashion, utilizing a TCM herbal "equivalent" to an antibiotic or a corticosteroid. Certainly, such products exist, and range from single herbs such as Mu Dan Pi (one of the most potent CS-like herbs utilized in Chinese medicine) or Jing Jie (utilized for its very potent antihistamine-like effects) to complete herbal formulations for the treatment of specific skin disease, such as Evergreen's Silerex or Herbal ABX, or Kan's Dispel Dampness and Nourish the Skin formula.

For chronic dermatologic cases, herbal therapy is one of my preferred modalities, so long as an appropriate TCM diagnosis has been established, the client has a clear understanding of the time frame required for resolution of the health challenge, and the client is prepared to accept a frequent recheck schedule. It is important to remember that herbal therapy does not equate with freedom from side effects, and the practitioner must always be ready to address these promptly. As patients move from resolution of their immediate symptoms to resolution of their underlying excess or deficiency condition, herbal doses will require modification. I find that even the most carefully prepared custom formula is seldom suitable for more than a period of 4 to 6 weeks in this later phase of treatment, and early on, I expect to recheck my patients every 2 weeks at minimum.

Learning which herbal formula to use for all cases of skin disease, and knowing how to use it and modify it over time, is an exhaustive process. There is no foolproof short cut to learning this information. However, even beginners can have good success by adhering to a few deceptively simple principles: if the skin disease is wet, dry it; if hot, cool it; if dry, moisten it; and in mixed presentations such as Damp-Heat, assess which presentation predominates, and treat accordingly. For example, if you have decided that your patient meets many of the criteria for Blood deficiency; you can feel quite comfortable utilizing a basic Blood deficiency formula, assessing at a 2-week interval, and modifying accordingly. Below, in alphabetical order, are some commonly used formulas and their indications

Chu Shi Wei Ling Tang

AKA: Eliminate Dampness & Harmonize the Stomach with Five Herbs & Poria Combination Also from the Golden Mirror, this formula enjoys substantial use in human medicine for herpes zoster. It is actually a combination of a combination formula, incorporating older formulas used to dry and drain dampness from the middle and lower Jiao (Wu Ling Tan for urination issues plus Ping Wei San and Wei Ling Tang for stomach issues). In our animal patients, it is used to treat relatively mild Damp Heat and Blood deficiency symptoms. Because it does contain some warming herbs to dry Dampness it is NOT suitable for patients with a strong Heat component to their skin disease. It is safe (and indeed often required) for long term use, but should NOT be used in pregnant animals.

Typical tongue and pulse findings: T - sticky yellow coat, P –slippery.

Clinical signs and associated health challenges: chronic GI signs (vomiting, reduced appetite, soft stools) mild damp heat signs, increased thirst or appetite, moist pyoderma, soft stools, sensitive to diet changes, yeast otitis, allergic dermatitis, mild pyoderma.

Long Dan Xie Gan Tang

AKA: Gentian Drain the Liver Decoction. This one is in most herbalists' "top ten" must-have formulas for the treatment of Damp Heat conditions anywhere in the body. First formally mentioned in the Analytic Collection of Medical Formulas, dating from 1682, this highly versatile formula treats Heat and Damp Heat especially well when it is of LIV or GB origin. Why is this formula so exceptionally useful? Consider the topical distribution of the liver channel, its association with the San Jiao channel via the GB channel (both are lesser yang channels), and the LIV association with the eyes, mood, and all three Jiao when its function is disturbed. Because the formula is so strongly cooling, it is not intended for long-term use, especially in cases with SP deficiency.

Typical tongue and pulse findings: T- Red, sticky yellow coating; P - Wiry, rapid, slippery.

Clinical signs and associated health challenges: red, itchy eyes, KCS, corneal ulcers, uveitis, acute glaucoma, severe pruritis, aggression, moist hot pyoderma, moderate to severe itch, yeast infections, epilepsy, allergic dermatitis, hepatic encephalopathy, vaginitis, cystitis, pyelonephritis

Qing Ying Tang

AKA: Clear the Nutritive Decoction. This useful formula was first described in Systematic Differentiation of Warm Diseases in 1798, a period of history when epidemics of infectious diseases were sweeping China and killing literally hundreds of thousands of people. It was developed to treat advanced cases of heat at the nutritive (Ying) and blood (Xue) levels of disease – the deepest levels of disease. At this advanced level of heat-associated disease, the Blood literally becomes "scorched" and stasis can result. Other formulas that address this deep level of disease are not frequently used today, because they contain ingredients that are banned, such as rhinoceros horn.

Tongue and pulse are characteristic of extreme heat and dryness: T - Dark red, dry; P - Rapid, thin.

Clinical signs and associated health challenges: irritability, severe heat, erythema, purpura, thirst, restlessness, severe intense itch, heat intolerance, severe systemic bacterial infections, hemolytic anemia, demodectic mange, severe deep pyoderma. Consider this formula for immune-mediated diseases such as immune-mediated thrombocytopenia (ITP), immune-mediated hemolytic anemia (IHA), and myositis, as well as for leptospirosis, encephalitis, and any severe vaccine reaction

San Ren Tang

AKA: Three Seed Decoction. A contemporary to Qing Ying Tang, and described at the same time in the same text, San Ren Tang is more specific for acute systemic contagious disease characterized by Damp Heat – in other words, at a less severe stage of disease, when the pathogen is still lodged in the Wei and Qi levels of the body. Often, these pathogens will enter via the Lu and ST and initial signs are referable to these organs and may be flu-like in nature: cough, dyspnea, vomiting, and loss of appetite.

Tongue and pulse are thus characteristic of Dampness in combination with Heat: T - Thin white coating, possibly lavender & swollen; P – Wiry to rolling, thin.

Clinical signs and associated health challenges: itch, agitation, hematuria, heat intolerance, crystalluria, moist or productive cough, greasy coat, mild to moderate damp heat accumulation, constipation, IBD, chronic conjunctivitis, asthma gastritis, seborrhea oleosa, fungal otitis, allergic dermatitis, cystitis

Si Miao San

AKA: Four Marvels Powder. This formula will either fall on your "always used" or "hardly ever used" list – there seems to be no middle ground. It is a derivation of Two Marvels Powder, described in 1481 in Teachings of Zhou Dan-Xi. Later, Three Marvels Powder was developed, and much later in 1904, Si Miao San was described. While it scarcely rates a mention in herbal formularies such as Bensky and Barolet, it enjoys wide use by some of the most highly regarded herbalists in North America, who use it for virtually any Damp Heat condition. Tongue and pulse signs are characteristic of Damp Heat as previously discussed. Clinical signs & associated health challenges: Heat intolerance, odorous gas, odorous skin, rounded abdomen, oily coat, vomiting, increased thirst or appetite, low back pain, elevated pancreatic enzymes, chronic GI complaints, degenerative myelopathy, IBD, otitis externa, allergic dermatitis, Cushing's disease, pododermatitis, anal sacculitis, epilepsy, recurrent pancreatitis, suppurative vaginitis, cystitis, colitis. With protracted Heat, hind limb atrophy and weakness of the lower back and legs can be seen.

Si Wu Tang

AKA: Four Materials Decoction. Dating from the same time frame as Shen Ling Bai Zhu San, and published in the 1000s in the Imperial Grace Formulary of the Tai Ping Era, Si Wu Tang is the classically recognized formula for Blood deficiency. In humans and in animals, Blood deficiency can result from inadequate diet, acute or chronic blood loss, or imbalances in any organ related to blood production; in TCM, this includes the SP, LIV, and HT. Si Wu Tang is not indicated for treatment of acute severe blood loss; rather, it is most specific for LIV Blood deficiency. In our carnivore patients, this is a common sequela to the practice of feeding a kibbled diet. The formula is highly Yin-nourishing and Blood tonifying, and is very suitable for long-term use. However, if the Blood deficiency has resulted in the invasion of EPFs other formulas may be more suitable. Because it is so Yin-nourishing, it is not suitable for cases SP Qi deficiency signs that have resulted in Dampness. Si Wu Tang is exceptionally effective in the treatment of reproductive disorders due to Chong channel stasis secondary to LIV Blood Stasis.

Typical tongue & pulse findings: T – Pale to lavender, depending on the degree of stasis; P – Thin and wiry to choppy, depending on the presence and degree of stasis.

Clinical signs and associated health challenges: anxiety, frequent dreaming, noise sensitivity, mild liver enzymes elevation, mild joint pain, infertility, seborrhea sick, keratoconjunctivitis sicca (KCS), and poor hair coat with low-grade itching. Allergic dermatitis signs, if present, are typically mild.

Si Wu Xiao Feng Yin

AKA: Four Materials Eliminate Wind Decoction. Known since 1742 when Golden Mirror of the Medical Tradition was published, this formula is eminently suitable for Wind Invasion, especially when secondary to Blood deficiency. Based on Si Wu Tang with a number of herbal additions directed at expelling Wind from the body, it is most suitable for short-term use until the Wind Invasion is resolved. Once this is accomplished, treatment needs to be redirected to address the underlying Blood deficiency. Si Wu Xiao Feng Yin should not be used in cases of Wind Damp Heat Invasion, as it can worsen the dampness symptoms. Tongue and pulse signs are similar to those seen in Blood deficiency. (Tongue and pulses more typical of Damp-Heat Wind Invasion would be more rolling and forceful, and skin pathology would be expected to be more pronounced).

Clinical signs and health challenges: Recurrent superficial pyodermas and otitis, papular rash in abdominal and inguinal region, low grade itching, fine dander, red, rough skin, dry coat, poor hair growth, staphylococcal hypersensitivity, allergic dermatitis.

Xiao Feng San

AKA: Eliminate Wind Powder. In use since the 1000's and published in The Imperial Grace Formulary of the Tai Ping Era, Xiao Feng San is a nicely versatile formula suitable for either Wind-Heat or Wind-Damp Invasion. When these EPFs enter the body, they become trapped under the skin. Especially if there is an internal pre-existing Damp-Heat condition, the EPFs settle deeper and transform into what is called "Wind Toxin." Extreme itchiness with weeping red lesions over large areas of the body is pathognomic for Wind Toxin. This condition can significantly injure both Blood and Yin, which then aggravates the itchiness and lends chronicity to this health challenge. Patients with Wind Toxin often traumatize themselves and develop significant secondary infections. Xiao Feng Yin treats both the immediate severe itch and the underlying deficiency. Faster results are often seen when it is both taken orally and applied topically as a paste o active lesions. One of my favorite single herbs, Jing Jie, is a chief herb in the formula; it has potent antihistamine effects.

Typical tongue and pulse findings: T - Variable with redness, with a white to yellow coat; P – Rapid and superficial.

Clinical signs and associated health challenges: Severe allergic dermatitis urticaria, eczema, psoriasis, ringworm.

Xiao Yao San

AKA: Rambling Ease Powder. Dating from the same time frame as Xiao Feng San, this formula's name derives from its effect on LIV Qi. When the SP is deficient, the LIV becomes less efficient at properly directing the spread of Qi throughout the body – it is constrained, resulting in typical SP deficiency GI signs combined with Blood deficiency signs.

Typical tongue and pulse findings: T – Pale, lavender, possibly swollen; P – Thin and soft.

Clinical signs and associated health challenges: LV/SP disharmony, abdominal pain, vomiting, constipation, diarrhea, abdominal distension, loss of appetite, lethargy, irritability, anxiety, IBD, allergic dermatitis, chronic active hepatitis. In humans, this formula is used successfully for treatment of fibrocystic breast disease, PID, optic neuritis, and central retinitis.

Yi Guan Jian

AKA: One Linking Decoction. Published first in the Continuation of Famous Physician's Cases Organized by Categories in 1770, One Linking Decoction is named for its utility in treating Yin deficiency of the LIV and KI with concurrent Qi stagnation. When LIV Yin is deficient, LIV Blood is also affected; the resulting deficiency is associated with pain along the LIV channel, stasis and heat accumulation, and eventually, epigastric pain with reflux.

Tongue and pulse findings are typical of deficiency and heat. T - Red or pale, dry; P - Thin, wiry.

Clinical signs and associated health challenges: powdery dander, elevated pancreatic and liver enzymes, hair loss, itching, irritability, chronic vomiting, allergic dermatitis, KCS, hepatitis, fear aggression, recurrent pancreatitis, separation anxiety, chronic active hepatitis.

TCM MANAGEMENT OF ATOPIC DERMATITIS

Deborah M. Mitchell, DVM, MS
Knollwood Hospital for Pets
Schaumburg, IL

In Stephen Covey's published data on time management for professionals, he references a four-part time management matrix (Figure 1). His matrix tool can be used to differentiate essential from nonessential actions that must be taken throughout the workday, and provides a framework for deciding upon the most time-efficient order in which to get them done. A version of his matrix appears below. His goal for most professionals? To "live north of the line" – in other words, to spend most of our working day proactively dealing with issues in Quadrants One and Two. By doing so, we can minimize the volume of interruptions from Quadrant Three and (hopefully) avoid being so overwhelmed that we take refuge in the time-wasters of Quadrant Four.

We can approach our treatment of atopy by use of a similar matrix. Many of the challenges we deal with in our atopic patients represent true "Urgent and Important" Quadrant One situations. They require immediate appointments and immediate diagnostics and therapeutics. Other patients—perhaps many—become Quadrant One patients because we failed to deal with their health challenges proactively in the past, to keep them from becoming emergency situations. (Many of our Blood Deficiency patients fall into this category.) Others represent patients we sometimes are tempted to deal with by benign neglect. Their owners frequently call at inconvenient times because, for example, their pet is keeping them up at night itching. These we often view them as Quadrant Three cases – Urgent, but Not Important. We prescribe a simple, immediate, and effective corticosteroid intervention to quell the itch. Then the patient re-presents a month later with a raging Damp Heat Quadrant One condition requiring immediate attention, extensive care, and a long period of follow-up.

Let's evaluate the dermatologic version of this matrix to re-prioritize how you could choose to treat your atopy patients. From a TCM perspective, are there Quadrant One patients? Certainly—and there are specific herbal remedies to address their needs. Therapy is likely to be short-term. When completed, we will need to address the underlying health issues that prompted the Quadrant One presenting status—otherwise, these patients will present repeatedly, acutely, and severely.

Quadrant Two is where TCM therapeutics definitely shine. This quadrant represents our opportunity for proactive, preventative, truly holistic care. Therapy is likely to be long-term, but can often eventually be replaced by careful and appropriate attention to diet and dietary supplementation.

Quadrant Three – Urgent and Not Important – represents another important opportunity for the astute TCM practitioner. By careful assessment of the underlying reasons behind minor nagging derm issues such as seasonal itching, we can often prevent these patients from becoming year-round medical nightmares.

What about Quadrant Four? From a TCM perspective, are there "Non-urgent and Not Important" medical issues associated with our atopy patients? I don't think so. Yet, until I learned TCM diagnostics and therapeutics, I had few good answers to give clients who complained that their pet sometimes smelled odd or had

Quadrant One **Urgent & Important** Crises, pressing problems, deadline-driven projects, meetings, and reports	**Quadrant Two** **Important, But Not Urgent** Preparation, prevention, planning for avoidance of crises and short deadlines
Quadrant Three **Urgent and Not Important** Needless interruptions, unnecessary calls, paperwork, e-mails, meetings; other people's minor issues	**Quadrant Four** **Not Urgent and Not Important** Trivia, busywork, irrelevant calls, paperwork, e-mails; time-wasters; 'escape" activities (TV, Internet)

Figure 1. Time management matrix.

a coat that wasn't shiny. Now, armed with a knowledge of tongue, pulse, and acupuncture point diagnostics, I truly believe I can say none of these patients have Quadrant Four problems. Quadrant Two is where these patients belong—along with appropriate herbal therapy and attention to diet and supplementation.

Quadrant One **Urgent & Important** Acute severe atopic flares QING YING TANG SI MIAO SAN LONG DAN XIE GAN TANG	**Quadrant Two** **Important, But Not Urgent** Proactive, preventative Tx SI WU TANG YI GUAN JIAN QI BAO MEI RAN DAN
Quadrant Three **Urgent and Not Important** "He's keeping me up at night with his itching" WEI LING TANG CHU SHI WEI LING TANG SAN REN TANG SI WU XIAO FENG YIN	**Quadrant Four** **Not Urgent and Not Important** "He's got a funny smell" "His coat isn't shiny" TCM: No such thing as a NU/NI !!!! Move to Quadrant Two

OZONE THERAPY: BEYOND OXYGEN. THE MOST NEEDED ADJUNCT TO VETERINARY MEDICINE

Margo Roman, DVM
Main Street Animal Services of Hopkinton (MASH)
Hopkinton, MA

Ozone is one of the most beneficial substances on this planet, and the BAD science you hear quoted on the news every night is causing you to subconsciously be afraid of nature, and therefore, a part of life itself. They tell you that somehow hydrogen plus nitrogen or sulfur equals ozone. $H + N + S = 0_3$? Not on this planet it doesn't! What is ozone? Simply, oxygen. Three atoms of nature's oxygen. It exists in a very active form for about 30 minutes before breaking down into two atoms of regular oxygen by giving up one atom of singlet oxygen. Where does ozone come from? Nature. And nature is efficient. The new growth in the forests, the trees, the grass on your front lawn, and the plankton in the ocean are continually creating oxygen.

If you have seen *Inconvenient Truth,* the Al Gore documentary on global warming, there is one scene that brings it all together. In one section he discusses the CO_2 levels over the Pacific Ocean. In addition to the original measurements that began in 1965, they were able to measure the levels from hundreds of years ago by taking samples from deep within glaciers. Gore shows a graph and needs to get on a mechanical cherry picker to show you the levels in 2006. The levels 5 years from now go off the screen.

What this clearly shows is that we live in an anaerobic environment very different than 40 years ago. CANCER Thrives on CO_2. Thus, if we live in an environment that has high CO_2 we can expect more cancer. Dogs and cats age 6 times faster than we do and their entire life is living within this high CO_2 level. Should we be shocked that 46% of dogs and 39% of cats are getting cancer? They are the canaries in the coal mine and are showing us what cancer rates will be in humans. The World Health Organization (WHO) estimates that the rate of cancer in humans will be 50% by the year 2020. We need to bring more oxygen to the tissues so they can respond.

Interestingly, in the news recently, they talked about how soft drinks, either diet or sugar-based, increased heart attacks. If you are ingesting CO_2 every time you drink, it may be what causes inflammation. Whether it is your heart or any of your tissue, you are putting yourself in an anaerobic state. That should be contrary to homeopathy as well. Giving yourself an oxygen state must be positive and thus helps the vital energy move towards healing by giving it more oxygen.

As you read this, this oxygen is rising up into the atmosphere to where the ozone layer is. In the region of the ozone layer, our rising oxygen is bombarded by the sun's photochemical energy in the form of ultraviolet (UV) rays. The UV energy bombardment changes the oxygen from O_2, two atoms of stable oxygen, into O_3, three atoms of unstable active oxygen. We call this pure form of oxygen "ozone." The using up of the UV rays to create ozone is how the ozone layer shields us from their harmful effects. This is all part of the natural process of life on this living biosphere called earth. The chemical formula for this is $3\ O_2 > UV > 2\ O_3$.

Bringing in ozone therapy into a veterinary practice is one of the best and easiest ways to enhance therapies which we may already be practicing. Wherever we have inflammation there is an increase in CO_2 in the tissue and oxygen would benefit healing in that location. After doing over 4,000 ozone treatments at my clinic, the overwhelming success is seriously noticeable. Veterinary medicine can enhance the healing of the body and its tissues with ozone. It is affordable, easy to administer and potentiates our medicine. It brings down the inflammation and disinfects with oxygen and no harsh chemicals

WAYS OF ADMINISTRATION

1. Saline 0.9% percolated with Ozone
   - Subcutaneous fluid given to patients which gets into the blood stream and through the blood brain barrier
   - Flushing external wounds
     - Hot spots, bite wounds, post surgical areas,
   - Flushing gums and mouth before and after dentals with or without extractions
   - Flushing eyes and other orifices
     - Eye injuries and infections
   - Flushing and cleaning ears
   - Flushing infected surgical sites including abdomen
   - Flushing urinary catheterized animal to bath the bladder and cleanse surface
   - Bagging limbs and flushing areas that have infections or inflammation
     - Interdigital infection, toe infections, wounds, pyoderma, *Malasezzia*, tumors
2. Insufflated rectally
   - For whole body administration
   - To get into an inflamed colon
   - Direct uptake into the caudal mesenteric vessels into the liver
3. Ozonated air bubbled through water and virgin olive oil
   - Auricular bagging or through a stethoscope
   - All the above limb bagging for a lessened ozone odor and lung irritation
   - Whole body bagging
   - Whole animal placed in a close cage
4. Ozoned water
   - Drinking directly after making
5. Intravenous treatments
   - In horses, IV catheter placed in jugular vein; using small 25-gauge needle bubbled as a pure O_3 gas toward heart slowly
   - Also given with ozonated saline charged

6. Prolozone prolotherapy with ozone as a flush behind the B12, procaine, dextrose, and Homeopathic Combination. Use equal volumes of liquid to ozone.

PRECAUTIONS

1. DO NOT breath ozone directly, because it will cause irritation in lungs. If taken within lungs must go through olive oil.
2. Having the pets on vitamin C or other antioxidants is important to protect against free radicals.
3. Some bleeding can occur with thrombocytopenic patients at the site of the subcutaneous administration.
4. Warn clients that the subcutaneous administration is cold and pets may squirm as if someone has but a cold towel on their back. Good distraction with cookies or upbeat conversations will help.
5. Some dogs seem to have itching at the site so allowing them to "shake it off" after is good.
6. Keep windows open or have a vented area when bagging, as it might cause some to have irritation of the throat.
7. Always check the connections of the silicon tubing.
8. Use only silicone tubing, because it will break down regular rubber and some soft plastic or latex.
9. Be careful to keep any equipment that has black rubber away from the ozone. That includes anesthesia breathing bags as it will break down the rubber.
10. Ozone will dissolve latex gloves when as a gas.
11. Do not leave the ozonator on without the oxygen connected
12. Always use 100% oxygen running through the ozone generator; do not use room air.
13. Some people are sensitive to the ozone so make sure your techs or client are not having any sensitivities.
14. When placing rectal catheter make sure after removing you pull the tail between rear legs to prevent "passing of the gas" before it has a chance to be absorbed.

SUGGESTIONS AND APPLICATIONS

1. Before bagging the ears or wounds first flush well with the ozonated saline to clean off the surface; making the surfaces moist also helps the process.
2. Use the largest needle to get the fastest fluid administration and therefore have less O_3 converting to O_2 in the plastic tubing.
3. Keeping the IV line attached with a needle will allow a more directed flush onto the eyes and any direct area
4. When loading a syringe, the ozone is heavier than air so you need to keep the needle opening upward. Placing a needle with cap on it gives you more flexibility to where it is placed prior to administering.
5. When starting a cylinder with 1000 cc of ozone allow it to perk for 30 minutes at 1/8 oxygen and 10 setting
6. Ozone will stay stable for about 30 minutes, so use it as soon as you can to get the maximum amount stored in the saline.
7. Ozone stays longer in glass than the plastic.Giving the ozonated fluids cooled gives you more time to assure that the O_3 is still present.
8. If you need to warm the fluids, take a thin water bottle filled with warm water and at the end of the IV drip wrap the plastic tubing around the bottle.
9. When bagging or whole body try to seal the opening to keep leakage to a minimum.
10. Attachment of energetic discs like tachyon around the cylinder might even energize the water even more.

CONDITIONS TREATED

1. All types of wounds, skin infections hot spots, pyodermas, abscesses, rashes, allergic dermatitis, insect bites, gangrenous lesions, deep abrasions with road dirt contamination, severe contusions de-gloving wounds, postsurgical flushing directly on incision and area treated.
2. Chronic and acute Lyme disease
3. Giving ozone before giving any acupuncture or homeopathy to make the tissue more hydrated and oxygenated
4. Acute and chronic kidney and liver failure
5. Pancreatitis
6. Viral and bacterial diarrhea
7. Spinal and head injuries
8. Musculoskeletal injuries
9. Cancer adjunct therapy
10. Stomatitis and gingivitis
11. Ocular irritations, allergic and infectious
12. Yeast-filled ears and both acute and chronic otitis
13. Upper respiratory conditions both viral and bacterial
14. Autoimmune conditions
15. To use instead of antibiotics if there has been a reaction or toxic reaction.
16. Potentiates the acupuncture, homeopathy and chiropractic and other modalities as it brings more needed oxygen to the body.

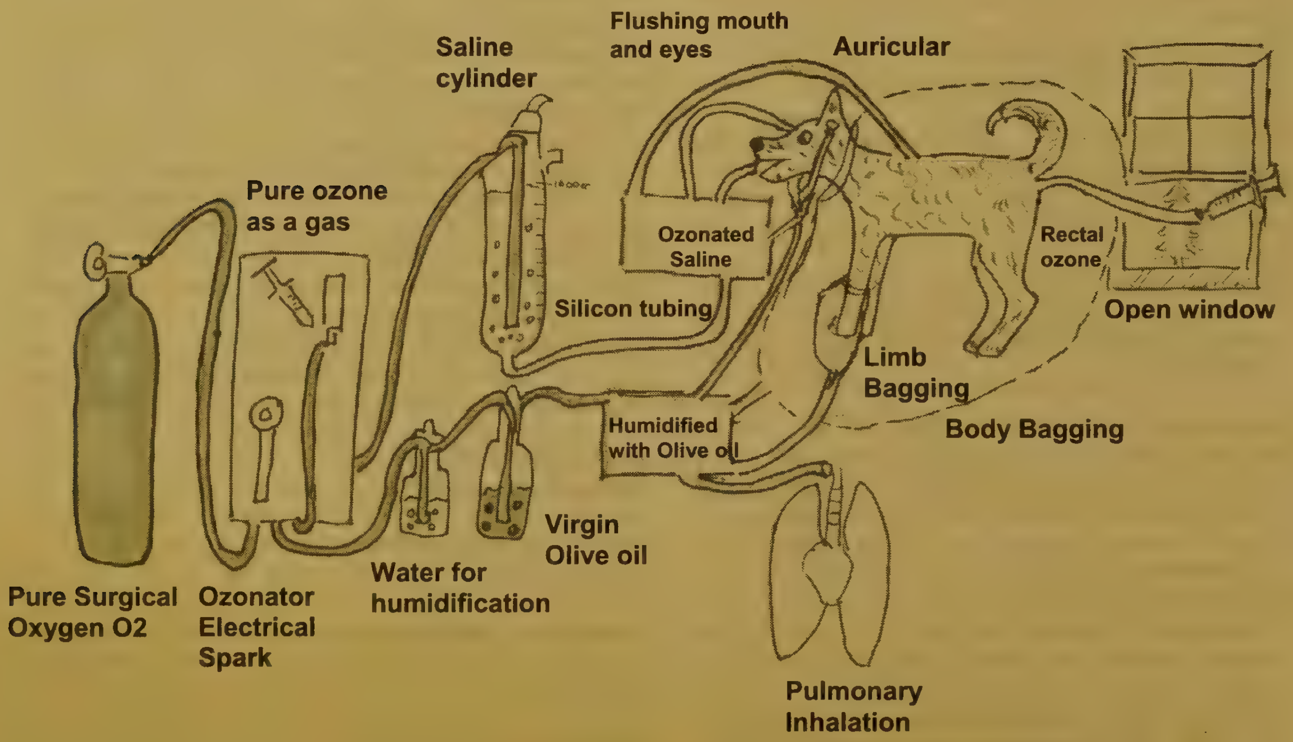
Table 1. Dosages and Settings for Ozone Therapy

IV fluids
Settings: Saline, 1/8 liter/minute and 10 setting

Animal's Weight (lbs)	Ozonated Saline (cc)	Restricted Amount (cc)	Rectal (cc)
10	70	40	25
20	100	60	45
40	140	100	60
60	200	140	100
80	250	180	130
100	300	200	140

Follow the recommended chart with your particular ozonator.
Ozone has the positive support for tissue repair and could be part of veterinary procedures.

Figure 1. Ozone therapy potentiates veterinary medicine healing with more O_2. After placed within body temperature it returns to 3 O_2 molecules



FOOD INTOLERANCE IN OUR VETERINARY PATIENTS

John B.Symes, DVM
Beltline Animal Hospital, PC
Mobile, AL

Chomp, chomp, chomp...*Gulp*. Slurp, slurp, slurp...*Belch*. This is the sound of "Fido" eating his scientifically formulated, well-balanced dog food. It can be purchased at the grocery store, but the discerning owner travels to the local pet shop to buy the better quality food. Most people know that you get what you pay for in a pet food and that the higher grade foods come from certain recognizable manufacturers and can only be found at specialty pet supply outlets. But, is that axiom really true? Does purchasing the most expensive food guarantee that your pet will be receiving the best in nutrition that the industry has to offer?

The unfortunate truth is that pet food is not as scientifically formulated, as most would like to think. For the most part, Fido's food is made with convenience and cost of manufacturing in mind more than science. Yes, the first few ingredients look appetizing enough and there are essential nutrients such as vitamins and minerals added to the mix. But are these ingredients natural for the pet and are they readily available for absorption and use by their body? Herein lies the crux of the matter.

The wake-up call comes when one realizes that once the meat source is removed from the diet, the remaining ingredients are mostly unnatural for the pet. If we exclude the beef, poultry, fish, and lamb, the remaining calorie sources are mostly wheat, barley, corn, rice, and oats, all of which are man-raised crops that the dog and cat would never consume in the wild. I love to inquire of my clients "How would a pet get rice? Swim to Viet Nam?"

But what is the problem with these complex carbohydrates being in the diet? Humans consume these with every meal and they are doing just fine, aren't they? Ahhhh. Are we??? If we were thriving on these things, those reading this article would be doing something else right now, wouldn't they? The problem is that the grains listed above cause some universal problems among humans and pets alike, as do a number of other problem foods and food additives that eclipse even the grains in their contribution to health issues.

To digress for just a moment, I have been a veterinarian for 28 years. However, seven years ago I had something come along that changed my entire life—professionally, physically, emotionally, and even spiritually. I finally found, for the better part of my life, that I have been suffering from celiac disease, otherwise known as gluten intolerance or gluten sensitivity. For forty-something years, I suffered like most other celiacs from a myriad of symptoms, including allergies, heart burn and intestinal problems, depression/chronic fatigue, insomnia, memory and balance difficulties, joint pain, and even fibromyalgia. I was taking at least four prescription drugs daily, was caffeine addicted, and was quite frankly not having any fun anymore.

Within four days of eliminating all wheat from my diet, the recovery began...and it was *dramatic*. On day four, I felt like I did not need coffee for the first time in twenty years. By the end of the first week, my long-term heartburn was gone and my IBS symptoms were coming to a screeching halt. By the end of the month, my fibromyalgia, back pain, insomnia, and chronic fatigue were well on their way to being nothing more than a bad dream. I was shocked and amazed at the results of simply eliminating this “staple” of my diet and this incredible recovery led me into seven years of intensive, broad-based medical research.

During this phenomenal time, I created a Website (www.Dogtorj.net) to chronicle my discoveries. From there, I began doing Internet interviews and consultations, which led to more discoveries while I was attempting to help both pets...and their owners...with their chronic medical problems. My life had become *very* different.

I am now almost seven years gluten, casein, and soy-free, off all drugs (prescription and OTC), symptom-free, and feeling better than I did when I was twelve. Yes, this miraculous recovery got my full attention as a patient and as a doctor. How could this be? How could I have been suffering from what millions of people and pets are still experiencing, and yet, be completely well in such a short period of time? How could all of these conditions be linked together? That’s what I am here to share with you.

What I hope to convey to you in these three articles is the incredibly far-reaching effects of celiac disease and the related food intolerances and how they have been playing a vital role in the demise of our health and that of our pets. We will start by discussing the “big 4”...gluten, casein, soy, and corn, or what I now lovingly term “the four horsemen of the apocalypse”...and the roles they play in chronic illness, epilepsy and other “idiopathic” conditions. We will take a little stroll down memory lane—one of those 20:20 hindsight things—that will hopefully turn your head around and amaze you as much as it has me. You will see what we did to veterinary and human nutrition that has changed the course of our medical histories.

In addition, I hope to convince those of you who do not already know that the elimination of the “big 4” can result in absolute medical miracles, with rapid and lasting recoveries ranging from simple allergies and intestinal disorders to refractory epilepsy, multiple sclerosis, and peripheral neuropathies. Proper nutrition, of course, has a major impact on not only the quality of life we enjoy but also the life expectancy of both humans and animals. I hope to demonstrate that the overall diet of both pets and people coupled with the far-reaching effects of the food intolerances represent the most important factors that we have under our immediate control that will affect our overall health.

I am sure that most of you are now aware of celiac disease. Most of us were taught about gluten intolerance in the Irish setter, although from the response I have received from colleagues and even those who taught me medicine in school, this has been long since forgotten. However, seven years ago when my brother, father, son, and I all discovered that we suffered from this condition, gluten intolerance was considered a "rare disorder, affecting less than 1:5,000 Americans." In my very first week of research, I found that celiac disease was being diagnosed in nearly 1:100 people in the United Kingdom, Italy, and Scandinavia. This, of course, was totally incongruous with what was being reported in our (human) medical literature in the US, especially once our common ancestry was taken into account. I also found that 40% of first degree relatives to a celiac would have the condition, a figure that certainly applies to my immediate family (and one that makes us take a second look at those ancestors). Needless to say, that obvious dichotomy also fanned the flames of my developing passion for this newfound research project.

My personal diagnosis of celiac disease came about in an indirect fashion through my brother's medical woes. He had been experiencing weight loss and severe abdominal pain for a few months and had made two or three trips to the emergency room for sharp, unrelenting discomfort. After a complete workup, including extensive blood work, MRIs, barium series, colonoscopy, and more, his doctors were at an impasse. The only abnormal finding was an iron deficiency anemia. Little did they know that they held the key to the diagnosis in their hands.

Out of the blue came an e-mail from a friend of his writing to Bob about celiac disease. This close friend was a medical researcher and Internet buff who came across this "disease" as a match for Bob's symptoms. My brother brought it in to me—his "doctor" brother—to read one day in my veterinary hospital. When I read the pages from www.celiac.com, my mouth fell open and I said "Well, Bob. This is you all right. Trust me. When this many things fit, it is the answer. But, Bob! This is not just you, this is *me*! It describes all of my symptoms perfectly." And it *did*. My chronic fatigue, irritable bowel, insomnia, heartburn, allergy symptoms, and even my fibromyalgia were described on those pages. I immediately committed to going off all foods with gluten as well as launching a full-scale investigation into this elusive condition.

In the first day of researching celiac disease, I experienced the beginning of what I would later call "the revelation." As I read about the diseases states from which the gluten intolerant suffered, the celiac was rapidly becoming the "who's who" of illnesses in humans...*and* animals. We were absolutely gobbled up with allergies, IBD, immune-mediated diseases, and cancer, while suffering from staggering rates of hypo- and hyperthyroidism (Grave's disease), diabetes, lupus, rheumatoid arthritis, intestinal lymphoma, colon cancer, and much more.

Armed with the newest information that the potential number of people with celiac disease was 1:30 people, and that a myriad of medical conditions had been linked to gluten intolerance, and that wheat alone made up a whopping 30% of the calories in the standard American diet (and was the primary ingredient in our pet's dry foods), I started to have medicine make sense to me for the first time in 20 years...and "the revelation" occurred.

"But how *could* something as simple as wheat and an item that was as much of a staple in our diets cause such huge medical problems?" I wondered. It did not take long to find "the answer" (which would become the title of my first major paper).

In celiac disease, *gluten is* the culprit. Gluten is comprised of two components, glutelins and prolamines, the latter being the most troublesome protein portion. Glutelins are simple proteins found in cereal grains that yield amino acids when hydrolyzed. Prolamines are the storage proteins of the grains and are insoluble in water but soluble in alcohol and dilute acids. Gliadin is the real problem among the prolamines and it is gliadin that is found in most of the immune complexes of the major diseases we will cover. It is antibodies to gliadin that are the principal diagnostic aid in celiac disease. At 69%, gliadin makes up the majority of the prolamine portion of wheat.

The immune response to gluten is often insidious yet potentially devastating. Gluten is an innately sticky glycoprotein (which is used to make industrial adhesives) and does adhere to cells lining the intestinal tract, particularly those of the small bowel. Villous atrophy of the duodenum and jejunum results from a complex of immune responses directed at gliadin in sensitized individuals. The resultant increase in gut permeability allows unnatural polypeptides to enter the blood stream in an abnormal fashion, entering the infant and adult alike in biological forms that were unintended. These various polypeptides have both direct and indirect effects that are harmful in a myriad of ways. We will discuss "lectins" in a moment, the term used to denote antibody-sized glycoproteins from various sources, particularly from the "big 4" foods (gluten grains, dairy, soy, and corn).

So, the basic pathophysiology of celiac disease is that the glue-like gluten adheres to the villi of the duodenum and jejunum and then induces villous atrophy in sensitized individuals. Once the villous atrophy takes place, a number of serious consequences follow with the most critical being a chronic, insidious malabsorption syndrome. (And *here* is where I get a little crazy.)

How many veterinarians and doctors remember being taught in medical school what the duodenum *absorbs* in the way of essential nutrients? Not many do, according to my numerous conversations with my colleagues and MD acquaintances. In fact, I have had board-certified doctors look me in the eye and tell me that the duodenum absorbs "nothing." Then, when I have pulled the stake out of heart, I diplomatically correct them by explaining that I, too, thought that at one time until I learned differently through my study of celiac disease.

The fact is, not only does it not absorb "nothing," it takes in the vast majority of our calcium, iron, iodine, B complex, vitamin C, and numerous trace minerals such as zinc, copper, magnesium, manganese, boron, lithium, and more. Once we see this crucial part of our medical puzzle, "the revelation" begins and other important parts begin to fall into place. Osteoporosis, iron deficiency anemia, thyroid disorders, immune incompetence, and enzyme deficiency all have much more palpable origins. And the reason why the celiac is the "who's who" of what goes wrong with a human (or any other simple-stomached animal that is afflicted) suddenly becomes quite clear. We are malabsorbing the nutrients that are essential to our well-being while being bombarded by proteins that our body's deem threatening. And that is why I often refer to the duodenum as "Pandora's box"—damage that area and we unleash the multitude of plagues that await us.

But here is the bad news: Gluten is not the only culprit. I also found *this* out the hard way. As I stated earlier, within days of eliminating all gluten (wheat, barley, rye) from my diet, I felt better than I had in years. Symptoms were disappearing rapidly and I was totally amazed, catapulting me into years of research and "consumer advocacy." Yes, I was hooked for life and accepted my new mission with reckless abandon.

The most pressing problem was figuring out what in the world I would eat. (Later I would write the paper "What in the World Do I Eat?") Surely I enjoyed the weight loss that quickly followed my new dietary commitment but some frustration set in as I scrambled to find "clean" (gluten-free) foods. I had always avoided cheese and eaten limited amounts of ice cream because of the battle of the bulge but, "Hey, I can eat all I want now because I'm losing weight and they are gluten-free." So, I started putting cheese on everything, drinking more milk, and eating a lot more ice cream as dessert. And, within weeks my symptoms were all coming back- the heartburn/IBS, headaches, joint pain, fibromyalgia, brain fog/depression, and insomnia. "What is up with this? Milk is supposed to be nature's perfect food." I quickly found out differently…and why.

Because I had found that wheat was the number two human, dog, and cat food allergen and that the culprit, gluten, was used to make industrial adhesives and that the allergies were formed at the time the damage was done to the gut, I naturally asked "Where is the 'glue' in milk?" That is when I found that gluten has an evil twin and its name is casein. I found that casein is the glycoprotein that makes up 80% of the protein content of cow's milk…and the one that Borden uses to make Elmer's Glue. "Ahhhh. Now we're onto something."

So, I eliminated all dairy products and, in a few short days, my symptoms were disappearing again. Within 3 weeks my chronic shoulder pain resolved, my sleeping improved, and I was feeling better than I had in my entire life. But the quest for what to eat had just gotten more complicated.

I began substituting soy products for the dairy-drinking soy milk, eating soy cheese, and having soy-based "ice cream" for dessert. However, within a couple of weeks, my stomach was in an absolute knot and many of my symptoms were returning, especially the pain and insomnia. "Now what is up with this?" I exclaimed. "I thought soy was supposed to be a health food." It took less than an hour on the Internet to be convinced that we had all been duped into thinking that soy was healthy for us. And yes, soy *is* used to make industrial adhesives as well. In fact, they make super-glues from soy, which are commonly used in the automobile industry (eg, to stick your rear-view mirror to the windshield).

When I eliminated the soy from my diet, my health returned and my research project expanded. As hard as it was to believe that the main three foods thought of by most to be among the healthiest things we can eat…wheat, dairy, and soy…were, in fact, the absolute worst possible things for many people to eat, this incongruity fit well with other things I was learning were upside down. These things included the aforementioned lack of knowledge concerning the duodenum's function, the true incidence of celiac disease, and the fact that we used fever-reducers to stop virus-induced fevers and carcinogens to treat cancer.

Therefore, I was not surprised to find that corn was the fourth guy on the list, rounding out the "four horsemen of the apocalypse," a term I love to use when being melodramatic or "prophetic." Once I had eliminated the first three "riders" I realized how crummy corn made me feel when I ate it. One more trip to the "glue" list and I found that they did indeed make glue from corn. The best they could do, however, was to put cardboard boxes together with it. "No wonder it was the most tolerable of the big 4." I thought. And, in fact, it is tolerated better by humans, dogs, and cats than are wheat, dairy, and soy. The history of the pet food industry sure proves this.

Now this part is really fascinating to me. The retrospective look at my veterinary career and the history of pet food ingredients dovetailed perfectly with my studies concerning food intolerance in people. When I graduated from veterinary school in 1979, the vast majority of pet foods were made with corn as the carbohydrate source. Pets were doing "OK" on these foods, with a rather select group of dog breeds having unusual difficulty with allergies, immune-mediated diseases, and early cancer-related deaths. Our allergy-suffering breeds were little white dogs like the Poodle and Westie. Other trouble breeds were Cockers, Beagles, Boxers, Golden retrievers, Irish setters, and German shepherds—those experiencing allergies, immune-mediated diseases, and higher rates of cancer. The average dog was reasonably healthy and allergies were just *a* problem within the dog world, not *the* problem. Immune-mediated diseases were something that we actually got excited about seeing as doctors and diagnosticians, not something that made us wonder what the world was coming to when we would later see them come in three at a time. Cancer was always a major cause of death of pets but, again, not something that we would, in the relatively near future, get so "ho-hum" about, seeing mast cell tumors every month and watching dogs drop like flies by age 6.5 years of bone cancer and lymphoma. Suddenly, we were talking about medicine during our lunch hours rather than our golf games or our significant other.

What happened? First of all, we had a "wheat glut" develop in this country. It was a definable geopolitical phenomenon that resulted in wheat becoming cheaper than corn. Suddenly, the pet food industry started to make food, particularly dried kibble, out of wheat instead of corn....and Pandora's box was opened. It was during this time that we adopted the "interesting" routine of mixing in a new food with the old for 3 to 4 days. Why did we do this? Well, if we didn't blend it gradually, the pet would often develop diarrhea or even vomit on the newly introduced food.

Now let me stop right here and ask an important question...or three? Where in the world were our brains at this time? Why did we not suspect that something might be wrong with the new food if it caused diarrhea, much less vomiting? Were we really *that* out of touch with medical reality? The thing that fooled us was the fact that the pet "adapted" to the food so quickly if we mixed it in. And, it seemed logical to mix in a new food, so "Problem solved!" right? But in retrospect, we were truly asleep at the wheel, not understanding the impact of the new wheat-based food and having long since forgotten our lectures on gluten intolerance in the Irish setter (if we ever got one). This went right over our heads, including that of yours truly. So, I am not throwing stones but "Man, were we stupid or what???"

But out of this quagmire arose what would become a giant among pet food companies—Hill's Science Diet. They claimed that their foods were scientifically formulated to produce less allergies, less skin problems, less intestinal upset, and even smaller stools. And they did! So, what did they do to accomplish this? Basically, all that they did was not take that big "left hand" turn that everyone else did choosing the wheat route and Hill's stayed on the corn road. How simple. How wise! Wow!!!

Yes, corn *was* better tolerated than was wheat. That did not make corn perfect by any means but comparatively speaking, it was heads and shoulders above this newest mistake that was being made—the single worst mistake made in veterinary nutrition—the transition to wheat-based diets. Thankfully, this came at the same time that we made one of the best decisions in pet nutrition—to take the dairy out of dog and cat foods. Many of you remember milk-coated puppy and kitten chows. Those my age will also be able to testify that they have seen a reduction in asthma, rheumatoid arthritis, and type 1 diabetes since the dairy was removed from these foods, especially when it is pointed out to them. In a medical study I found 4 years ago, it was boldly stated that our children who get cow milk in the first five days of life have a 40 to 50 times higher rate of these three conditions. Understanding lectins (which we will cover later) will pull this all together for you.

And in retrospect, the trouble breeds mentioned above do have more problems with corn to this day (and maybe more, thanks to the genetic modification of today's corn. Do you remember CRY9C or "Starlink" corn and the Taco Bell shell recall a few years ago?). I believe that it is highly likely that the "big 4" food intolerance share the genetic tendency that celiacs experience in that 40% of first-degree relatives will have the condition. Therefore, I recommend the elimination of corn from the diet of all pets (and people who will listen) but particularly from that of the breeds mentioned above. I have now developed a strong suspicion of corn intolerance in these breeds by doing food allergy tests and seeing a high rate of corn allergies among them.

Thankfully, there are those in the pet food industry who are wising up, with more and more of them proudly stating and displaying on their bags "no wheat, no corn, and no soy." Unfortunately, they know that wheat is a problem but they obviously don't understand *why* it is so harmful or *why* it is now the (new) number one food allergen in dogs and cats. They turn right around and use barley and rye—the other two gluten grains—as substitutes. They must not understand celiac disease and the fact that the allergies are formed at the time the gluten induces the villous damage. Is that really the extent of their nutritional research?

It must be quite limited as dairy products are making a major comeback. (Errrrh!!!) Yes, even some of the most dedicated and "holistic" pet food companies are utilizing cottage cheese, skim milk, and yogurt in their newest formulas. When I call or write to these companies, they try to ease my dissatisfaction by stating that it is all lactose-free. Once again, is that the extent of their research on the topic of dairy intolerance? Do they not know that lactose is just a little 'ol sugar and that the proteins in cow milk, particularly casein (and even more specifically alpha s-1 casein), are the true culprits? Unfortunately, many are under the misconception that lactose is the main issue in milk.

However, as celiac disease becomes better known (and the awareness of this all-too-common condition is rising rapidly), the truth about casein, soy, and corn intolerance will finally emerge. *Then*, we will have "the four horsemen" on the run and people will learn that they *do* have their health destinies, as well as those of their pets, more in their own hands than they have ever believed.

VIRUSES AND LECTINS – THE MISSING LINKS

John B. Symes, DVM
Beltline Animal Hospital, PC
Mobile, AL

The role of viruses and lectins in the development of disease has been one of the most amazing topics that I have researched over the past seven years. I include these together because there is a fascinating interaction between these two entities that helps to explain many of the conditions we still refer to as "idiopathic," a term to which I now take exception. The only concept that upsets me more is "autoimmune disorder," a term that implies that our immune system does not know what it is doing. I wholeheartedly disagree with that premise and a better understanding of viruses and lectins supports my dissent.

Let's start with lectins. In my quest for solutions to "idiopathic" problems, the study of these antibody-sized proteins/glycoproteins yielded answers to many of the questions that were haunting me as I tried to explain how my dietary changes could yield such phenomenal results. Lectins are carbohydrate-binding glycoproteins or proteins that are ubiquitous in nature, with plants, animals, and even bacteria producing these remarkable compounds. Although the true role of lectins in plants is still under investigation, we know that these proteins play numerous important roles in animals and humans. They serve to bind circulating glycoproteins to cells, such as those in the liver, to facilitate their removal. Our body produces lectins that are involved in immune responses (eg, mannose-binding lectin), the adhesion of cells, and the removal of pathogens through binding to carbohydrates on their surfaces. In the case of neurons, the oligodendrocyte produces two different lectins—one that helps nourish the neuron and another that can kill it. Bacteria produce lectins that enable them to adhere to tissue. Finally, certain foods contain lectins that can do serious harm to susceptible individuals. Therefore, there are "good" and "bad" lectins in nature—those that promote health and others that contribute to disease.

For the purposes of this discussion, the focus will be on those dietary lectins that have been directly linked to illness in animals and humans. The most common sources of damaging lectins are the gluten grains (wheat, barley, rye), dairy products, legumes (eg, soy, peanuts, beans), and corn. The nightshade family (tomatoes, potatoes, peppers, eggplant and tobacco) also contain potentially harmful lectins, most of which are inactivated by cooking but to which some individuals can become quite sensitive (eg, arthritis). For example, uncooked wheat flour, beans, and eggplant are considered toxic while heating them removes most, but not all, of the harmful lectins. Fermentation, sprouting, and soaking have also been employed to remove these harmful substances. But I frequently tell people to think "peanut allergy" when considering the degree of sensitivity that some individuals develop to these proteins.

The literature describes the pathomechanism of the damage done by these lectins as being like a lock and key, in which the circulating lectin serves as a key that unlocks the cell to which it attaches. All complex cells, plant or animal, have carbohydrates that project from their cell membranes. These serve as glycoprotein receptors (docking stations, if you will) to which circulating lectins and other things can attach. When the right "key" comes along, its attachment can initiate a cascade of events in that cell wall that may lead to a number of different outcomes, ranging from the attraction of the immune system and cell death to the production of hormones and chemicals to the multiplication of that cell.

Once I found that these harmful lectins (especially those from gluten, dairy, soy and corn) could cause inflammation and tissue damage all by themselves, without an immune response, things really started to make sense. The immune response is actually *secondary* to that damage, which helps to explain why we see such a variation in the *measurable* response in different individuals challenged by these glycoproteins. Some will respond with an outpouring of antibodies yielding positive tests while others will not, thus helping to explain the negative tests in individuals who ultimately respond quite well to the elimination diet when they employ it despite those negative tests.

It then becomes clear that these dietary glycoproteins are also a big part of what we label as "autoimmune disease." Personally, as I stated at the outset, I do not like nor do I use that term anymore unless I put it in quotes. That term implies that the immune system is attacking its own host's tissues for no good reason. I contend that this does not happen...ever. The immune system *always* responds appropriately but we simply do not always fully understand why it does what it does. The inflammation being incited by lectins is a prime example of this.

As stated, lectins are antibody-sized entities. How would we know they are present when they are, in fact, that small? We can't see them in a routine tissue sample. It would take biochemical analysis or, again, antibody testing to determine whether they are involved. Therein lies the rub. Not everyone responds with what we might call an "appropriate" response (one that we can detect readily). We just have to know that these lectins can and *do* cause changes in the individual cells of the body (neurons, nephrons, blood cells, etc.) of susceptible individuals. I contend that the "big 4"—gluten (from wheat, barley, rye), dairy, soy and corn—are not healthy for anyone. They are simply better tolerated by some than others. This is the nature of "spectrum disorders" among individuals, who range in affliction from the "best of the best" to the "worst of the worst." Once again, thinking "peanut allergy" helps us to envision the "worst of the worst." Now that's a sensitivity!

For the sake of previous discussions on the dietary aspects of epilepsy, does gluten affect neurons? It definitely can. Can gluten *kill* neurons? Yes, indeed! If an inquiring individual were to do an Internet search for "gluten, neurons," they would find some very relevant articles. How the lectins of gluten damage and kill neurons is the interesting thing, and the answer lies in understanding of the mechanisms of cellular physiology and how that cell responds to challenges. A concurrent study of viruses helps to complete the big picture and that is why I write so much about this on my site now.

It is logical that the viruses *inside that cell* are among the things that determine the response of that cell to the challenge by lectins, carcinogens, and other chemicals/pollutants/preservatives, etc. It has been described in the literature that a cell can have as many as ten different responses to a lectin challenge, ranging from cell death (apoptosis) to tumor formation. I believe that one of the answers lies in the adaptive viruses found inside that cell. After all, that is what viruses do in nature—they facilitate adaptation (as well as cause variation in nature).

The phenomenal thing is that our very DNA contains these adaptive viruses. Researchers now estimate that up to 45% of the genetic codes in our double stranded DNA are actually viral information, some active and some extinct. This is what retroviruses, in particular, do. They infect the cell and incorporate their genetic information into our DNA. That is why these particular viruses are involved in cancer and why cancer *can* be "genetic" (inherited). This “genetic” information can then be transmitted vertically to offspring.

As heretical as it may seem, I am now convinced that cancer itself is an adaptive process. The viruses that "cause" cancer are simply adapting to the challenges (eg, carcinogens) that we keep throwing at them. When all else fails, they cause the cell that they are designed to protect to start growing out of control in order to ensure the survival of that virus and the cell itself. Thus, I now view a tumor as a “protective cocoon.” Is this a radical idea? Yes, it is. Does it make sense once it is understood that viruses are vital to the normal function of plants and animals (including humans) and that their main purpose is to facilitate adaptation? It certainly does to me.

So why don't we all have cancer and develop it early in our lives? Once again, because there is another part of the "syndrome" that is necessary—a weakened immune system. That’s right. We are all killing cancer cells right now (hopefully). The immune system recognizes when a cell is trying to do something inappropriate or harmful and sends in the cavalry. This could be just what we (incorrectly) label as an "autoimmune response." Once again, I contend that the body *does* know exactly what it is doing each and every time it does something. Again, we just don't understand what it is doing sometimes and I believe that what we call “autoimmune disease” is one of those times.

How does this apply to epilepsy and other neurodegenerative diseases such as multiple sclerosis, Alzheimer's, Parkinson's, and ALS? As stated above, some viruses have a distinct affinity for the central nervous system. The two most common brain tumors in veterinary medicine are the oligodendroglioma and astrocytoma, both of which are likely to be viral neoplasms involving those cells that control many of the supportive functions of the neuron, including the production of the myelin sheath and the control of neurotransmitter levels (glutamate). If there are viruses in those cells causing tumors, then through "reverse engineering" we can see that there are going to be the processes (eg, "autoimmune diseases") taking place that precede the formation of these tumors because these are the means by which the immune system controls the tumor production...until it is overwhelmed by all the toxins we are throwing at it.

Latent viruses are involved in many of the disease "syndromes" with which we are afflicted, including epilepsy and cancer. I like to use cancer as the parallel to illustrate the difference between "causes" and "triggers." For example, carcinogens do not “cause” cancer. Viruses are the principle, *proven* cause of cancer (eg, retroviruses). Carcinogens simply incite the virus into causing that cancer. I am convinced that the public will be told in the (near) future that all cancer is viral. Researchers have been saying this for years and years. After all, it is what some viruses do, incorporating their DNA into that of the host only to have that cell reproduce out of control at a later date. It is those ugly chemicals and pollutants we call carcinogens that trigger those viruses into turning the DNA into a cell factory.

But, viruses and carcinogens alone are not sufficient for the individual to develop cancer. The host must also experience some degree of immune failure in order to get the "big C." So, it is this triad of factors...viruses, carcinogens, and immune failure...that come together to yield the resulting cancer. That is what we call a "syndrome."

Epilepsy is also a syndrome and the parallel is probably already quite clear. Most individuals are loaded with viruses that have the potential to cause seizures. In humans, Epstein-Barr (EBV) is one such Herpes virus; 50% of our children in the US have Epstein-Barr by age 5 and 95% of Americans over age 40 have this virus in their body. Many epilepsy sufferers have not ever been told that viruses are known causes of seizures. The fact is that there are over 25 viruses *known* to causes seizures in people, many of which are ubiquitous, including Epstein-Barr, Herpes simplex, measles, mumps, Coxsackie viruses, and many more). Of course, measles and mumps are in the paramyxovirus group, to which the virus of canine distemper belongs.

But why don't all humans have seizures if EBV can cause them? One explanation would be that most individuals don't have the right cofactors in place to make it happen. And there are many cofactors in epilepsy: Diet, the existence of food intolerance (eg, celiac disease), air quality, hormonal influences, lifestyles, and many other things that affect the immune system as well as the health of the central nervous system, liver, kidneys, and endocrine systems, all of which can play vital roles.

Of all of these factors, diet is clearly the most important. This is very easy to see once we understand what is required of our brains, bodies, and immune systems in order to stay healthy and operate optimally. The "big 4" (gluten, dairy, soy, and corn) are the “who's who" of what is wrong with foods, as they damage our gut's ability to absorb nutrients (eg, celiac disease), shower our body with damaging proteins (lectins), load us up with staggering levels of "excitotoxins" (glutamate and aspartate), and pound us with estrogens. As a result, tissue health suffers, immunity fails, enzyme systems go down, and the Pandora's box of viruses is opened wide.

Many of the viral infections acquired by humans and pets during their lifetime do not come and go but rather come and *stay*. As I am fond of saying, "If I could do a Star Trek type of scan on your body and give you a print out of the viruses you have in there, once you got over the shock of that news, you might just be motivated to take better care of yourself, eh?" Some infections are "diphasic," with the initial infection causing some signs while other symptoms arise later once the individual fails to control the initial infection or continues to bombard these viruses in situ with things that "make them mad."

A number of these viruses have an affinity for the glial cells (astrocytes and oligodendrocytes) that support the neuron and regulate the levels of neurotransmitters (eg, glutamate) at the synapse. I contend that this is one of the main reasons why "the G.A.R.D" (the glutamate/aspartate restricted diet) works so well to help control seizures, as it dramatically reduces the work load of these dysfunctional cells and puts a great Band Aid on the epilepsy situation. But, the long-term solution comes from the very same diet (also called the gut absorption recovery diet), which helps to reverse the malabsorption/malnutrition syndrome that ushered in immune failure and tissue ill health that set the stage for the viral uprising.

The bottom line is that viruses don't like certain things hurled at them (eg, lectins, chemicals, and pollution). Their first reaction is one of adaptation, enabling the target cell to function in the presence of the offending agent. For example, I believe that seizures actually serve a purpose by effectively disposing of the excess glutamate that could otherwise kill the neuron. Glutamate is not only neurostimulating but potentially neurolethal, as illustrated by the fact that brain death results from the "glutamate cascade" regardless of the cause of bodily death.

However, when viruses are called upon to repeatedly react to these noxious stimuli, a more involved form of adaptation is employed and one that draws the attention of the immune system. At this point, the individual had better hope that there is a competent immune system present to put down this "rebellion." If not, that candidate may suffer the full blown syndrome, whether it be "refractory" epilepsy, cancer, or that myriad of things researchers love to call "autoimmune disorders." These things are not as "idiopathic" as we have all been led to believe.

Our medical histories all line up with this once the role (and ultimate *purpose*) of viruses in nature and our bodies is grasped. They are not the malicious entities that we have labeled them to be. They are simply doing their job. The noxious stimuli being thrown at them is the real issue. We are literally *forcing* them into becoming pathogens. In addition to the plethora of obvious offending agents being imbibed, most individuals are compounding matters through poor nutrition, polluted environments, fast-paced lifestyles, and lack of sleep. All of these things add up to self-induced misery.

Our pets may not be out partying all night but the two most important—their horrific commercial diets and polluted environments—are wreaking havoc of their health. Is it really their "genetic makeup" that is cutting their lives so woefully short? Do "genes" ultimately turn on all of us? If so, why do they wait years to make that turn? If something is genetic, why does it take 10, 40 or 80 years to show up? What is waiting? Why does it wait? What brings it out of hiding? I have suggested many times that, when reading a paper on genetics, the word "gene" be replaced with the word "virus" to see if that treatise makes more sense. Suddenly, answers to the above questions start coming. Coupled with the knowledge of viral stimulants (eg, carcinogens, lectins, and other viruses), we can start to see what…or who…the real culprit is.

As the cartoon character Pogo so wisely stated years ago, "We have met the enemy…and he is *us*."

IDIOPATHIC EPILEPSY— THE DIETARY SOLUTION

John B.Symes, DVM
Beltline Animal Hospital, PC
Mobile, AL

One of the earliest and most dramatic findings in my seven years of research into these food-related issues was the phenomenal response to elimination diets in those suffering from idiopathic epilepsy. In my initial study of celiac disease, I came across accounts of epileptic children with gluten intolerance showing significant improvements when placed on gluten-free diets. As most epilepsy in pets is considered "idiopathic" in the veterinary literature, this caught my attention. I also read that MSG (monosodium glutamate) and aspartame had been identified as seizure triggers in children with epilepsy. It did not take long for me to see that gluten was absolutely loaded with the parent non-essential, neurostimulating amino acids glutamate (glutamic acid) and aspartate (aspartic acid). "Could it be that simple?" I asked myself. "Could the brain be too unhealthy in some individuals to handle these amino acids in common foods? Could the "bound" forms in those food sources do to those individuals what the "free" and concentrated forms found in common food additives do?" I came across the work of Dr. Russell Blaylock (*Excitotoxins – The Taste That Kills*) in which he clearly states that MSG and aspartame have been linked to numerous neurological conditions, including migraines, epilepsy, and neurodegenerative diseases. "But could the bound forms in food really do the exact same thing?" was my question.

This seemingly novel question was quickly answered with a resounding "Yes!" The very first epileptic dog I put on a gluten-free diet stopped seizing within 48 hours. Surpassing my newfound expectations, every single case of idiopathic epilepsy (and even some cases of brain tumors) that I put on a gluten-free diet had a significant response. And with a little more research, I was able to determine what was required to completely halt the seizures in those that did not respond as well as I had come to expect. There were a number of other culprits to be identified—namely, casein, soy, and corn—as well as other foods rich in these two amino acids. But what do these phenomenal responses say about the true cause of idiopathic epilepsy?

Well, what do we know about epilepsy? It is the most common neurologic condition worldwide. This is also true in dogs. 50 million people are afflicted with epilepsy at any given time. In humans, epilepsy typically strikes between 2 and 14 years and then again after 65. Seizures usually start in the dog between 6 months and 6 years. The age of onset and the fact that developing countries have a much higher incidence than developed ones suggest an "opportunistic" disease state to me, one that preys upon an immature or inefficient immune system. And yet, the majority of epileptic cases are still classified as "idiopathic."

Fact: There are over 20 viruses that have been shown to cause seizures in people, including many that are ubiquitous and known to have latent states, with Epstein-Barr, other herpes viruses, influenza, Coxsackie, measles, and mumps being among them. Now I do not plan to turn this into a virology lecture but will simply state that I am personally of the opinion that chronic latent viruses which have an affinity for glial cells are the main underlying cause of idiopathic epilepsy. My website goes into great detail as to why I am convinced of this.

So, if viruses are the true cause of idiopathic epilepsy, where do the "big 4" foods come into the picture? One of the key points that my research revealed is that the "big 4" (gluten, casein, soy, and corn) are the main foods that induce villous atrophy of the duodenum, the principal lesion found in celiac disease. This is a crucial fact to grasp because that particular area of bowel has the vital role of absorbing many essential nutrients, including calcium, iron, iodine, B complex, vitamin C, zinc, copper, magnesium, and much more.

How hard is it to imagine the far-reaching and potentially devastating effects of the villous damage induced by these foods? In fact, there is no tissue or bodily function that does not depend on these nutrients for optimal performance. The brain, liver, immune system, and every other organ and enzyme system could suffer when this sort of chronic malabsorption takes place. And the celiac experiences it all. That is why I often refer to the duodenum as "Pandora's box"—damage it and we unleash the plagues that await us.

And, why these are the main four foods that damage this area is equally fascinating. These are the only four foods that we consume from which adhesives are made, with gluten and casein being used to make industrial glues and bases for paint. Casein, which makes up 80% of the protein fraction of cow's milk, is the protein from which Borden makes Elmer's glue. As most of you know, powerful super-glues are made from soy with which much of your car is assembled. But the best they can do with corn adhesives is to put cardboard boxes together with it. And in examining these four foods, it is interesting to note that corn is the best tolerated.

A good example of a secondary problem resulting from this villous damage is reduced serotonin production. 98% of the body's serotonin is produced by the enterochromaffin cells that line that same area of gut that is damaged by the "big 4." The other 2% is produced by the brain itself from tryptophan. However, in both areas, B complex is utilized as a coenzyme to make that conversion. But where is that B complex absorbed again? Yes, B complex is absorbed primarily by the duodenum. Thank Goodness some is absorbed sublingually. And serotonin is not only a mood moderator but plays a role in moderating the neurostimulating effects of glutamate at the synapse. I certainly believe that serotonin deficiencies play a vital role in the severity of epilepsy. Celiacs are notoriously low in this vital hormone, as illustrated by their depression, bleeding tendencies, high rates of epilepsy, and severe immune-mediated diseases.

The fascinating thing to see is that these four gut-damaging foods are also the leading dietary sources of the non-essential, neurostimulating amino acids, glutamate and aspartate. They are also rich in tissue-damaging lectins, food allergens, and estrogens. I've come to understand that this is no coincidence. "Lectin" is the term given to antibody-sized glycoproteins that occur in nature, being derived from foods, bacteria, and even our own cells. For example, the oligodendrocytes in our brain are capable of producing two different lectins, one that supports the neuron and one that can kill the neuron it serves.

The lectins that pertain to this discussion are those derived from foods and the astute reader already suspects that the main players are those derived from the "big 4": Gluten grains, dairy products, soy, and corn. All complex cells have glycoprotein receptors on their outer cell wall, to which "dock" things like antibodies, viruses, and lectins. When a lectin docks to a receptor, any one of ten different reactions can take place, from cell death to tumor formation. In between are inflammatory reactions, the production of hormones, and changes in the cell wall. Dr. D'Adamo based his eating-for-your-blood-type work on lectins, noting that certain blood types were more prone than others to the different glycoproteins of dairy, wheat, soy, and corn.

On that note, how *does* a cell know which is the appropriate response to this non-living entity? I contend that it is the *viruses* in that cell that determine the response. These viruses can force that cell to adapt or they can make that cell grow out of control, which we call tumor formation, a process that I believe is the viruses' ultimate adaptation. The role of lectins helps to explain much about the celiac's medical history, including their staggering rates of immune-mediated diseases and certain cancers.

So once again, we see that the foods that are unhealthy for us are so in numerous ways and are practically screaming out to us to stop eating them, often beginning in childhood with colic, congestion, asthma and other allergies. As I mentioned in my first article, I found a study a few years ago that found our children who get cow's milk in the first five days of life had a 40 to 50 times higher rate of asthma, type 2 diabetes, and juvenile onset rheumatoid arthritis. My study of lectins certainly supported this and I recommend everyone learn as much about these antibody-sized glycoproteins as possible. And the allergies to these foods are primarily formed at the time the damage to the gut takes place as a prelude to the showering of the body with these damaging lectins, which have their hand in a wide range of immune-mediated disorders. The estrogens these foods contain add significantly to the problem, as estrogens are both inflammatory and immune suppressive.

But for the topic of epilepsy, I will focus on the glutamate content. The foods richest in glutamate are the gluten grains (wheat, barley, and rye), dairy products, beans and legumes (especially soy and peanuts), nuts and seeds, and foods prepared with the "free" form known as MSG. Meats are also rich in glutamate content but alone do not do any intestinal harm. It is the combination of the villous atrophy, damage to the cells that covert glutamate to glutamine, and the rich glutamate content of the "big 4" that distinguish them as the main culprits.

I *have* done my homework, finding sites that list the glutamate and aspartate content of common foods and making tables and charts to give to interested parties, mainly to illustrate the fact that the main food allergens are also the culprits here, while the universally healthy food-namely fruits and veggie- are lowest in these non-essential amino acids. Some things do make sense.

As I mentioned, I have been treating epileptic veterinary patients for several years employing a glutamate/aspartate-restricted diet (now known as "The G.A.R.D.") with phenomenal success. In fact, I have yet to have a case that did not show significant improvement, most of which stopped seizing within 48 hours and only had recurrences when the owners were non-compliant. My (free) Internet consultations during those years have generated some fascinating human testimonials by those who have applied these principles on their own. Both children and adults have responded dramatically, just as my early study about celiac epileptics suggested.

One extremely important personal discovery was a seizure pattern of the un-medicated epileptic dog, which showed that the typical interval between eating a high glutamate meal and having a seizure was 4 to 6 hours (as opposed to a 30 minutes to an hour interval seen when people ingested the "free" forms, MSG and aspartame.) This 6-hour lag time is consistent with the effects these same foods have on the human "insomniac," who eats dinner and dessert at 7 to 8 PM and awakens each night at 1 to 2 AM. The parallels are obvious.

By applying The G.A.R.D., we put an immediate Band-Aid on the situation by dramatically reducing the glutamate load on the diseased neurons, liver, and intestinal cells. This has halted seizures, literally overnight, in otherwise refractory seizure patients. Again, I cannot over-stress how well this has worked. But the long-term recovery of the epileptic comes from the same restrictive dietary approach, as it allows the gut to heal and function better. This includes the return to proper nutrient absorption as well as the production of serotonin and melatonin, two hormones that are vital to our health, especially to that of the central nervous system. That is why I now also refer to The G.A.R.D. as the "gut absorption recovery diet."

Of course, epilepsy is not the only neurologic disorder that is affected by the downward spiral created by these trouble foods. The "excitotoxins" are vitally involved in ADHD, migraines, pain syndromes (eg, fibromyalgia) and neurodegenerative diseases such as ALS and Alzheimer's. Again, Dr. Blaylock has pioneered much of this work. Now imagine the brains of those individuals with food intolerance that have been afflicted by nutrient malabsorption their entire life. Then, throw in the deleterious effects of fast food, hydrogenated oils, and polluted environments while folding in our fast-paced lifestyles, lack of restorative sleep, and overuse of symptomatic medication and we have a recipe for disaster. Our current medical dilemma really should be no mystery at all.

And the *real* problems begin in "Pandora's box." The "Big 4" are the "Who's Who" of unhealthy foods and celiacs are the "martyrs," showing the world just how bad things can get when we eat something that our body no longer wants. In the sensitized individual, these foods can induce villous atrophy with the resultant malabsorption syndrome compromising the entire body including the brain, liver, and immune system. They also cause the release of histamine, which increases the permeability of the blood brain barrier thereby allowing more of the excitotoxins into the brain. Furthermore, these foods are loaded with those harmful lectins on which Dr. D'Adamo has written volumes of great information. And last but not least, the gluten grains, dairy and soy are also suppliers of medically significant amounts of dietary estrogens, which can be both chronically inflammatory and immune suppressive—a deadly combination when viruses are in play. Their role in breast cancer is well established.

The "four horsemen" are wreaking havoc on countless lives and now we know exactly why. They are particularly nasty when it comes to neurologic conditions, ranging from simple depression/chronic fatigue to severe neurodegenerative disorders. Their bombardment of the brain with lectins and excitotoxins (once the brain has become adequately diseased) clearly precipitates the seizures seen in idiopathic epilepsy. I now view epilepsy as a "syndrome" but these trouble foods have their hand in multiple aspects of that syndrome. And *dramatic* recoveries can occur when the "Big 4" are eliminated from the diets of afflicted individuals. However, epilepsy is just "the hook" as I like to term it. It is simply a glaring example of the vast array of conditions in which food intolerance has its hands.

It has become painfully clear to me that a proper diet has more potential to prevent and treat disease- as well as extend life expectancy—than anything else under our immediate control. Once again, we do have our health destinies in our own hands.

PROLOTHERAPY – A SIMPLE, NATURAL TECHNIQUE THAT STIMULATES THE BODY TO REPAIR DAMAGED/LOOSE LIGAMENTS

Carvel G. Tiekert, DVM
Bel Air, MD

HISTORY

Prolotherapy (sometimes known as *regenerative injection therapy* and more inaccurately as *sclerotherapy*) is not new. The concept of irritating tissue to promote healing dates as far back as the ancient Greeks and our old friend Hippocrates, who treated Olympic javelin throwers with unstable shoulders by touching with what he described as a "slender hot iron" to the ligaments holding the shoulder joint together. The heat would irritate the ligament capsule, causing it to tighten up.

Prolotherapy was used in France to treat hernias before modern surgical techniques became available.

The techniques we use today were developed in the 1930s by G.S. Hackett, MD, a surgeon from Ohio, along with other MDs and DOs. The same techniques subsequently have been used successfully for pain relief from ligament laxity for nearly 60 years.

Hackett coined the term "prolotherapy" because his initial work demonstrated that the new tissue laid down during the healing process was new healthy tissue, not scar tissue. (This distinguishes prolotherapy from a related treatment known as "sclerotherapy.") "Prolo-" stands for proliferative, implying that new cells and collagen fibers are proliferating and growing. The term "regenerative injection therapy" which is now being used by some practitioners is fairly new and is an attempt to portray more accurately what is actually taking place physiologically.

VETERINARY HISTORY

For years pin-firing and blistering in horses (oddly enough called counter-irritants) were commonly used techniques. They were essentially a type of prolotherapy. They have fallen into disrepute, and while I'm not an equine practitioner, I suspect that prolotherapy in selected cases would be a useful technique in horses.

A short paper entitled "Electrosurgical Treatment for Cranial Cruciate Ligament Rupture" was published in the June 1979 VM/SAC in their clinical briefs section. Since it is such a short piece I have reproduced it in entirety:

> Two prevalent methods for dealing with cranial cruciate ligament rupture in dogs are reconstruction and imbrication. Both are involved and expensive procedures. Electrosurgery is a simple alternative and does not obviate a surgical approach.
>
> With the dog under thiamylal sodium anesthesia, the stifle area is prepared aseptically, and a 1/32"x 3/4" straight needle (Cameron Miller) is applied to the skin, down to the periosteum, in a line-firing pattern at points 1/2" apart, from the humeral epicondyles to the tibial condyles. Five to six holes usually suffice in each of 4 lines: 1 each craniad to the lateral and medial collateral ligaments, respectively, and 2 over the cranial aspect of the stifle (Figure 1).
>
> This procedure produces an *acute inflammation, resolution of which results in functional stability of the joint within a week*. In 6 of 94 cases the procedure had to be repeated, but none has required surgery after electrocautery.

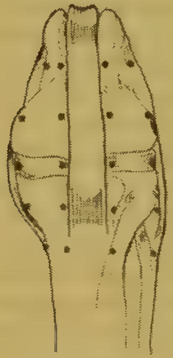


Figure 1.

SCIENTIFIC EVIDENCE

Hackett was the first to demonstrate clinically and scientifically a method of strengthening ligaments, and was the first to coin the word *prolotherapy*. He showed that by creating controlled inflammation permanent increases in ligaments size (35% to 40%) resulted. He reported an 82% patient-reported cure rate of backache in a series of 1,600 patients treated with prolotherapy. His final examinations were performed from 2 to 12 years following the conclusion of injection therapy, thus indicating the permanency of the treatment.

More recent studies have confirmed his initial studies. In 1983, Liu et al. injected a proliferative solution (aodium morrhuate) into rabbit medial collateral ligaments (MCLs) of the knee. The ligaments showed a significant increase in ligament mass, thickness, ligament-bone junction strength and weight-to-length ratio compared to controls. This effect was confirmed by Maynard et al in 1985 in his study on Achilles tendons in rabbits. In a human study in 1989, Klein et al. documented cellular evidence of new collagen growth when comparing pre- and postinjection sacroiliac ligament.

PHYSIOLOGY

In a sense, prolotherapy creates an injury. Figure 2 shows schematically what happens during healing. Cellular debris and humoral factors at the injury site attract an initial influx of granulocytes. The granulocytes proceed to secrete a number of factors, among them proteolytic enzymes, which debride to wound area and attract other cells. Ultimately fibroblasts are recruited and are stimulated to produce new intracellular matrix, including new collagen. As this collagen is produced it creates tissue remodeling and strengthening of the area, including the wound contraction we see in Figure 2. This contraction of the wound as a result of the production of new collagen/ligaments creates a tightening of the wound, and reduction in joint laxity and therefore the reduction in pain. The whole process is called the *wound healing cascade*, and, in the very basic model that is very briefly described above, is characteristic of all healing wounds.

THOUGHTS ON OTHER ASPECTS OF THE RATIONALE FOR THE THERAPY

A number of years ago Sharon Willoughby, DVM, DC posited that a major reason for the spinal arthritis that we see in big dogs was to some level of joint laxity in the articular facets of the vertebrae. This led to the body's only response to an appropriate function – inflammation.

A series of articles by Kealy et al In JAVMA reported on 48 Labrador retrievers in a long-term split-litter study where one dog in each pair was fed 25% less food than its pair mate from 8 weeks of age until death. In the limited fed dogs there was significantly less (75% less at the five year mark) arthritis than in the full fed group. In a recent conversation with one of the authors I was told there will be further papers generated by this long-term study looking at various orthopedic aspects of the study. Could it be that growing slowly allowed the ligaments to grow appropriately along with the bones and muscles?

A recent paper by K. Dean Reeves, MD, and Khatab M. Hassenein, PhD (*Alternative Therapies* May/June 2003) entitled "Long Term Effects of Dextrose Prolotherapy for Anterior Cruciate Ligament Laxity" has a title that tells most of the story.

TECHNIQUE

This is one of the simplest therapies that you can use. Prolotherapy (which I had first heard about in the 1980s) had sat on the shelf until a number of years ago since I was having good luck with the electrosurgery procedure mentioned above. Through a variety of personal medical issues the therapy came off the shelf and I began to explore it for myself. When I reached a physiatrist (MD pain management specialist) his first comment to me was "You're a vet–do it to your self. I'm 80 miles away from you." I did find someone closer that did some work with me as a patient. He also became to some degree a mentor, giving me books and pointers. The whole experience got me started with the procedure.

To be successful with prolotherapy, it is critical that **you know your anatomy**. It will not be effective if you don't get the solution where it needs to be—that is, into the ligament and at the boney interface of the ligament.

In our practice we use 15% dextrose as our predominant injection solution into the ligaments, and 25% into the joint (see Figure 2).

ANESTHETIC COMPLICATIONS

Christine Egger, DVM, MVSc, CVA, CVH,
Diplomate ACVA
College of Veterinary Medicine
University of Tennessee, Knoxville, TN

Many anesthetic drugs decrease cardiac output (CO), blood pressure (BP), heart rate (HR), tidal volume (TV), respiratory rate (RR), and body temperature (BT) regulation. Complications arising from the surgical procedure itself may result in further depression of CO and ventilation. The early sympathetic nervous system (SNS) reactivity to hypoxemia, hypercarbia, hypotension, and reduced tissue perfusion is reduced under anesthesia, and there is limited ability to compensate. Monitoring of oxygenation, ventilation, and arterial blood pressure are critical, as impairment of the cardiovascular and pulmonary systems can rapidly result in cardiac arrest.

RESPIRATORY COMPLICATIONS (See Table 1)

General Effects of Anesthesia on the Respiratory System

- V/Q (alveolar ventilation to perfusion ratio) mismatch, due to alveolar hypoventilation, reduced pulmonary perfusion, and shunting of pulmonary blood, is common.
- Functional residual capacity (FRC) is reduced, particularly with the patient in dorsal recumbency.
- When FRC is close to or less than the closing volume of the lung, the small airways close, resulting in atelectasis, right to left shunting of blood in the pulmonary vasculature, and hypoxemia.
- Brainstem respiratory centers are depressed by general anesthetics and mu agonist opioids, resulting in a shift in the CO_2 response curve and reduced hypoxic respiratory drive.
- Reduced compliance and increased resistance of the thorax and lungs results in a change to a diaphragmatic breathing pattern.
- Cilial paralysis, mucosal drying, and depressed airway protective reflexes also impair respiratory function.

Hypoxemia

- One of the most immediately life-threatening complications that occur under anesthesia is hypoxemia.
- Hypoxemia is identified from an O_2 saturation (SaO_2) <90%, or a PaO_2 < 60 mmHg.
- Mild arterial hypoxemia (PaO_2 < 60 mmHg; < 8 kPa; SaO_2 <90%) causes activation of the SNS.
  - Early clinical signs include restlessness, dysphoria, tachycardia, dysrhythmias, and hypertension.
  - Hypoxemia initially causes stimulation of respiration and increased minute ventilation
  - Cheyne-Stokes breathing pattern may be observed.
  - HR, stroke volume (SV), myocardial contractility, and CO increase.
  - Systemic vascular resistance (SVR) increases and mild hypertension may occur.
- With moderate arterial hypoxemia, (SaO_2 60–80%), local vasodilation may predominate and SVR and BP decrease.
  - HR may continue to increase because of the baroreceptor reflex response.
- With severe hypoxemia (SaO_2 < 60%), local depressant effects predominate and BP falls rapidly, the HR slows, shock develops, and ventricular fibrillation or asystole follow.
  - Inadequate supply of oxygen to the brain stem results in hypoventilation and apnea.
  - CNS depression, bradycardia, hypotension, and cardiac arrest are terminal signs.
- Hypoxemia promotes cardiac arrhythmias (usually ventricular), due to a decreased myocardial O_2 supply-demand ratio.

Airway Obstruction

- With obstructed airways, animals ventilate to minimize the resistance work of breathing, resulting in a reduced RR and increased TV to maintain minute ventilation.
- Many anesthetic drugs cause increased relaxation of pharyngeal tissues, causing further obstruction.

Upper Airway Obstruction (Inspiratory Dyspnea)

- Partial obstruction results in inspiratory stridor with slow, deep breaths. Paradoxical breathing may be observed.
- Full obstruction results in pronounced paradoxical breathing and hyperextension of head and neck. No inspiratory stridor may be heard.
- The upper airway may undergo a dynamic inspiratory compression.
- Pulmonary edema and acute lung injury can result.

Lower Airway Obstruction (Expiratory Dyspnea)

Restrictive Pulmonary Disease:

- Decreased lung compliance and increased lung elastance can result from restrictive diseases extrinsic (ie, pneumothorax) or intrinsic (ie, pneumonia) to the lungs.
- Restrictive pulmonary diseases result in the lungs collapsing and becoming less compliant.
- This increases the work of breathing to overcome the elastic forces and expand the lungs, and a rapid shallow breathing pattern is adopted.

Hypoventilation/Hypercapnia (reduced minute ventilation: reduced TV and/or RR)

- End-tidal (ET) CO_2 or $PaCO_2$ > 45 mmHg (6 kPa) is indicative of hypoventilation.
- Patients receiving 100% oxygen under anesthesia are less likely to become hypoxemic during hypoventilation, but patients that are on room air (21% FIO_2) will.

- Hypercapnia impairs oxygenation by displacing oxygen in the alveolus with the high concentrations of CO_2, resulting in decreased alveolar and arterial oxygen concentration.
- Hypercapnia causes direct depression of cardiac and vascular smooth muscle and reflex stimulation of the SNS.
- Mild hypercapnia ($PaCO_2$ 45-60 mmHg) results in mild SNS stimulation, tachycardia, mild hypertension, stimulation of respiration and an increase in minute ventilation
- With moderate to severe hypercapnia ($PaCO_2$ 60-85 mmHg), SNS stimulation first results in tachycardia and hypertension, increasing myocardial O_2 demand, and later results in decreased myocardial O_2 supply, due to tachycardia and hypotension. CNS depression occurs.
- With severe hypercapnia ($PaCO_2$ > 90 mmHg), severe CNS depression occurs, respiratory stimulation is reduced, and apnea occurs.
- Hypercapnia can also cause ventricular arrhythmias.

CARDIOVASCULAR COMPLICATIONS (See Table 2)

General Effects of Anesthesia on the Cardiovascular System

- Many anesthetics (volatile and injectable) produce a dose-related:
  - Depression of left ventricular (LV), right ventricular (RV), and left atrial (LA) myocardial contractility (negative inotropy) by altering intracellular Ca^{2+} homeostasis.
  - Decrease in LV diastolic function (negative lusitropy).
  - Decrease in LV afterload due to vasodilation and a reduction in SVR.
  - Depression of baroreceptor reflex control of BP.
- These effects result in reduced venous return, hypotension, bradycardia, and a decrease in CO, and are exacerbated in a failing heart.

Cardiac Dysrhythmias

- Bradydysrhythmias
  - Severe bradydysrhythmias can greatly reduce CO, BP, and tissue perfusion if there is limited ability to increase contractility or increase venous return by vasoconstriction.
- Atrial Tachydysrhythmias:
  - Severe tachydysrhythmias reduce CO and tissue perfusion due to decreased time for diastolic filling, reduced ejection time, reduced time for coronary perfusion, and myocardial ischemia.
- Ventricular Dysrhythmias
  - Common types of ventricular dysrhythmias seen under anesthesia include PVCs, ventricular tachycardia, and ventricular fibrillation and can dramatically decrease CO.

Hypotension

- Pathophysiology of hypotension:
  - BP is the force driving tissue perfusion, and a MAP of at least 60 mmHg and an SAP of at least 80 mmHg is necessary for perfusion of the brain, heart, and kidneys.
  - Adequate BP does not always indicate adequate CO and tissue perfusion; significant vasoconstriction will result in a high BP, but CO and tissue perfusion may be low.
  - Hypoperfusion of vital organs and the extremities results in inadequate tissue delivery of oxygen and removal of waste products, and clinical signs of shock and subsequent organ dysfunction.
- Treatment of Hypotension:
  - Reduce amount of injectable or inhalational anesthetic by administering additional analgesics with MAC-sparing effects (mu-agonist opioids, ketamine, lidocaine).
  - Bolus IV administration of 20–30 mL/kg of balanced, isotonic, crystalloid solution (attempt 1–2 times), or 5–20 mL/kg of colloid solution (maximum 20 mL/kg/24 hr) to increase intravascular volume (if no underlying cardiac disease or oliguric or anuric renal failure).
  - Correct hypoxemia, hypercapnia, acid–base, and electrolyte disturbances.
  - Provide sympathomimetic support–anticholinergics, vasoconstrictors, and positive inotropes.

Hypertension

- Arterial BP is the most important determinant of left ventricular afterload and cardiac work.
- Hypertension (MAP > 100 mmHg and SAP >160 mmHg) results in increased myocardial work and increased myocardial oxygen demand, which could result in myocardial ischemia and cardiac dysrhythmias.
- Hypertension can result in retinopathy, blindness, and renal failure.
- Sudden hypertension during anesthesia indicates SNS stimulation, and possible causes must be ruled out.

Table 1. Common Respiratory Complications of General Anesthesia

Clinical Sign	Etiology	Rule-outs	Treatment
Dyspnea: **Obstructive Pulmonary Disease**	Upper airway (inspiratory dyspnea)	Brachycephalics Soft palate entrapment Laryngeal or tracheal obstruction Laryngeal paralysis Head bandage too tight Kinked ET tube	Oxygen Extend head and neck and pull tongue forward Suction airway Endotracheal intubation Steroids and diuretics +/- sedation
	Lower airway (expiratory dyspnea)	Bronchospasm Asthma, COPD Anaphylaxis	Oxygen Bronchodilator Steroids, Antihistamines
Restrictive Pulmonary Disease (rapid, shallow breaths)	**Intrinsic:** **Extrinsic**	Pulmonary edema, pneumonia, infiltrates, ARDS Pneumothorax, pleural effusion, increased intra-abdominal pressure	Oxygen Thoracocentesis Endotracheal intubation IPPV Alveolar recruitment maneuver
Hypoxia	V/Q mismatch and right to left intrapulmonary shunting	Apnea/hypoventilation Atelectasis Inadequate FiO_2 Airway obstruction Restrictive lung disease Severe anemia Severe hypotension Cardiac arrest	Oxygen Endotracheal (ET) intubation and IPPV Alveolar recruitment maneuver Reversal of CNS depressant drugs Thoracocentesis Bronchodilators, Diuretics Hemoglobin transfusion Sympathomimetic support +/- CPR
Hypoventilation	Reduced FRC Reduced minute ventilation (RR or TV)	Positioning Relaxation of respiratory muscles Resp. depressant drugs Abdominal distension Hypotension, Hypothermia Airway obstruction	ET intubation IPPV Reverse respiratory depressant drugs if effects are severe Reduce abdominal distension Correct hypotension, hypothermia Correct airway obstruction
Respiratory Arrest	Depression of brainstem respiratory centers	Overdosage of anesthetics Reflex apnea Brain stem injury Cardiac arrest	ET intubation IPPV CPR
Hyperventilation	Increased minute ventilation (respiratory rate and/or TV)	Inadequate depth of anesthesia Hypercapnia, hypoxemia Hyperthermia	Increase depth of anesthesia if required Check absorber granules, one-way valves, fresh gas flow, and the breathing circuit
Aspiration	Aspiration of GI contents Aspiration of blood, saliva, mucus, or pus	Drugs that lower LES tone Factors that delay gastric emptying (pain, fear, opioids) Increased intra-abdominal pressure (pregnancy, ascites, GI obstruction) Prolonged anesthesia	Appropriate fasting Rapid IV induction and control of airway in fed patients Pre- or post- treatment with prokinetic drugs, H-2 blockers, or proton pump inhibitors Position head down to allow drainage Suction and lavage of esophagus Sucralfate

Table 2. Common Cardiovascular Complications of General Anesthesia

Clinical Sign	Etiology	Treatment
Bradydysrhythmias • Sinus bradycardia • A-V block (1° or 2°) • Sinus arrest • Atrial standstill	Potent mu opioids High vagal tone Hypothermia CNS disease & increased ICP Hyperkalemia Addisonian crisis	Anticholinergic Butorphanol or naloxone to reverse mu opioid effects Warm patient Decrease ICP Correct hyperkalemia
Tachydysrhythmias • Sinus tachycardia • Atrial tachycardia • Atrial fibrillation	Drug induced (atropine) SNS stimulation: pain, hypoxemia, awareness, hyperthermia, anemia, hypotension, hypovolemia Myocardial disease	Rule out and treat underlying cause Beta blockers (esmolol or propranolol)
Ventricular dysrhythmias • Ventricular premature contractions • Ventricular tachycardia • Ventricular fibrillation	Hypoxia, myocardial ischemia, traumatic myocarditis, GDV, splenic disease, hypercapnia, acid–base imbalance, electrolyte imbalance, drug effects (thiobarbiturates)	Rule out and treat underlying cause Lidocaine, procainamide, Mexilitene Magnesium sulphate CPR
Hypotension (Bradydysrhythmias and Tachydysrhythmias can also contribute to hypotension and should be ruled out and treated)	**Decreased venous return:** • Vasodilation • Hypovolemia • IPPV • Pericardial effusion • Tension pneumothorax • Closed pop-off valve • Surgical packing and retraction of organs • Severe bradycardia	Increase intravascular volume with balanced, isotonic, crystalloid or colloid administration Thoracocentesis Pericardiocentesis Open pop-off valve Reduce surgical traction Reduce mean airway pressure and the I:E ratio with IPPV
	Vasodilation (volatile anesthetics, propofol, and thiopental cause vasodilation)	Administer a vasoconstrictor: • Dopamine • Ephedrine • Epinephrine • Vasopressin
	Ventricular dysfunction	Administer a positive inotrope: • Dobutamine • Dopamine • Ephedrine • Epinephrine
Hypertension	Pain Hypoxemia Hypercapnia Metabolic acidosis Underlying renal or cardiac disease	Rule out and treat underlying cause Beta blockers ACE inhibitors

Table 3. Emergency Drugs Used During General Anesthesia

Drug	Indications	Dose	Possible Side Effects
Atropine	Bradycardia AV block Sinus arrest Ventricular asystole	0.01–0.02 mg/kg IV	Tachycardia Central cholinergic syndrome
Aminophylline	Bronchospasm Asthma Anaphylaxis	0.2–0.6 mg/kg	Tachycardia Dysrhythmias Hypotension
Albuterol	Bronchospasm Asthma Anaphylaxis	0.15 mg/kg Inhaled	Tachycardia Dysrhythmias Hypotension
Calcium	Known hypocalcemia Calcium channel blocker overdosage	1 mL/9kg 10% CaCl 1 mL/2.3 kg Calcium gluconate	Bradycardia Dysrhythmias
Corticosteroids	Anti-inflammation Stabilization of blood vessels Analgesic	Dexamethasone: 0.5–1 mg/kg IV Methylprednisolone: 20 mg/kg IV	Infection GI or renal ischemia
Diphenhydramine	Antihistamine	2.2 mg/kg IV or IM	Hypotension if given rapidly IV
Dobutamine	Hypotension Myocardial dysfunction	2–10 μg/kg/min	Tachycardia Dysrhythmias
Dopamine	Renal failure Hypotension Myocardial dysfunction Vasodilation	2–20 μg/kg/min	Tachycardia Dysrhythmias
Ephedrine	Hypotension	0.03–0.06 mg/kg IV	Tachycardia Dysrhythmias
Epinephrine	Hypotension Refractory bradycardia Anaphylaxis CPA	0.01–0.2 mg/kg IV/IO/IT 0.01–0.03 μg/kg/min	Tachycardia Dysrhythmias
Esmolol	Beta-blocker Hypertension Tachycardia	50–200 μg/kg/min	Hypotension
Furosemide	Diuretic Pulmonary edema Cerebral edema Laryngeal edema	1–2 mg/kg IV	Excessive diuresis Hypokalemia
Glycopyrrolate	Bradycardia	0.01 mg/kg IV	Tachycardia
Isoproterenol	Refractory bradycardia Ventricular asystole	0.01–0.1 mg/kg/min	Hypotension
Lidocaine	Ventricular premature contractions Ventricular tachycardia Ventricular fibrillation	1–2 mg/kg IV 20–100 μg/kg/min	Bradycardia Hypotension Seizures
Magnesium chloride	Given with prolonged CPA or intractable Ventricular fibrillation	1–2 ml/20 kg over 10 minutes	Hypotension CNS depression
Procainamide	VPCs Ventricular tachycardia Ventricular fibrillation	10–20 mg/kg/hour	Bradycardia Hypotension Seizures
Terbutaline	Bronchospasm Asthma Anaphylaxis	0.01 mg/kg IV	Tachycardia Hypotension Dysrhythmias

Table 3. Continued.

Sodium Bicarbonate	Metabolic acidosis During CPR: • If pre-existing metabolic acidosis • >10 minutes of CPR	0.5 mEq/kg IV over 20–30 minutes Use	Metabolic alkalosis Respiratory arrest if given too quickly Hyperosmolality
Vasopressin	Vasodilatory shock (sepsis) Ventricular fibrillation unresponsive to defibrillation or epinephrine.	0.5 units/kg once	Severe vasoconstriction Dysrhythmias

LOCAL AND REGIONAL ANESTHETIC AND ANALGESIC TECHNIQUES

Christine Egger, DVM, MVSc, CVA, CVH
Diplomate ACVA
College of Veterinary Medicine
University of Tennessee, Knoxville, TN

- Provides more effective analgesia
- Allows the use of lower doses of drugs, resulting in fewer adverse effects
- Significant "MAC sparing" effects, allowing the use of lower concentrations of inhalant anesthetics
- Combinations of local anesthetic/opioid, local anesthetic/alpha-2 agonist, or opioid/alpha-2 agonist can provide multi-modal analgesia

DRUGS USED FOR LOCAL AND REGIONAL ANALGESIA AND ANESTHESIA

Local Anesthetic Drugs

- Block nerve conduction in all types of neurons (all pain fibers (A-delta and C fibers), motor and sympathetic neurons).
- The drug must penetrate the connective tissue sheath to reach the neuronal cell membrane, where it blocks the generation and conduction of nerve impulses by inhibiting voltage-gated sodium channels.
- Because they block all pain fiber (A-delta and C fibers) transmission, they provide excellent pre-emptive analgesia and markedly reduce MAC.
- They also block motor and sympathetic neurons and can produce hypotension and paralysis of intercostal muscles and the diaphragm, with epidural or intrathecal administration.
- Onset and duration of blockade differs by anatomical location, fiber type, and frequency of stimulation.
  - Fibers innervating more proximal regions are more superficial in the nerve bundle, so are blocked first, with more distal regions blocked later.
  - Myelinated A-delta (pain) sensory fibers are blocked first, followed by larger sensory A-beta (touch, pressure) and A-alpha (motor) fibers, with small unmyelinated C fiber (pain) blockade occurring last.
  - Neurons in damaged tissue discharge at higher rates, so are more susceptible to blockade.

Dosage and Uptake

- Absorption across mucosal, pleural, and peritoneal surfaces is rapid, with peak plasma concentrations achieved within 10 minutes and high bioavailability.
- Absorption from subcutaneous sites is slower, with lower bioavailability.
- All local anesthetics cause vasodilation, which makes absorption of the drug more rapid.
- Epinephrine may be added to slow absorption, but should never be used for blockade of distal extremities because of the potential for local tissue ischemia.
- Base dosage calculations on lean bodyweight, and always calculate total safe dose to avoid toxicity.
  - The maximum recommended dose of bupivicaine and articaine is 4 mg/kg in dogs and 2 mg/kg in cats, and of lidocaine, is 8 mg/kg in dogs and 6 mg/kg in cats.
    - Lidocaine 2% (20 mg/mL) – duration 1–1.5 hours
    - Lidocaine 2% (20 mg/mL) with epinephrine – duration 1.5–2 hours
    - Bupivacaine 0.5% (5 mg/mL) (Marcaine®) – duration 4–6 hours
    - Articaine 4% (40 mg/mL) (Septicaine®) (with epinephrine) – duration 4–6 hours

Toxicity

- Overdosage results in cardiac depression, hypotension, seizures, coma, death.
- Animals with questionable liver function should be dosed carefully, as toxic doses are lower.
- Inadvertent IV injection of bupivicaine, which is highly toxic to the cardiovascular system and CNS (decreased contractility, dysrhythmias, decreased cardiac output, hypotension, seizures, coma), can result in cardiovascular collapse; **always aspirate syringe prior to injection of any local anesthetic to avoid IV or intra-arterial injection.**
- Allergic reactions can occur, but are uncommon.
- Although all local anesthetics can cause tissue irritation, very concentrated local anesthetic solutions (lidocaine 5%) are very irritating to tissues and neurotoxic, resulting in permanent conduction blockade.

Opioids

- Block primarily C fibers, and do not block A-delta, motor or sympathetic nerve fibers
- The analgesia from opioids is less profound, but still very effective
- Morphine is often injected into joints and is used for epidural analgesia.

Incisional Line Block

- Use before surgical incision, or after surgery and before skin closure.
- Use a 25-gauge, 1-inch hypodermic needle and a syringe.
- Insert the needle subcutaneously after a sterile prep, and inject prior to incision or before complete closure.
- Aspirate prior to injection and inject along the entire incision, fanning out your injections and aspirating back as you move the needle.

- Bupivacaine (0.5%), Lidocaine (2%; with or without epinephrine), or Articaine (4%) can be used at 0.2 mL/kg or 0.1 mL/lb
- You may use a larger volume, if necessary, as long as you stay below toxic doses.

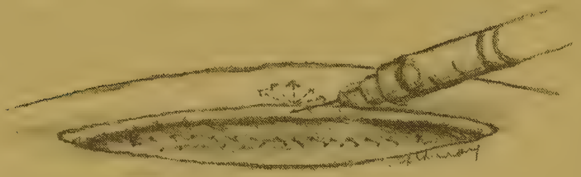

Figure 1. Incisional line block.

Intra-articular Stifle Block

- This block is used for analgesia of the joint before (pre-emptive analgesia) or after surgical intervention.
- Clip and aseptically prepare the joint
- Insert needle lateral to the patellar ligament
- Aspirate to ensure placement
- Inject drug:
  - Lidocaine, bupivicaine, or articaine (0.2 mL/kg or 0.1 mL/lb).
  - Morphine (0.1 mg/kg) can also be used alone, or in combination with a local anesthetic.
- Alternatively, this block can be place intra-operatively, after closure of the joint and before skin closure.

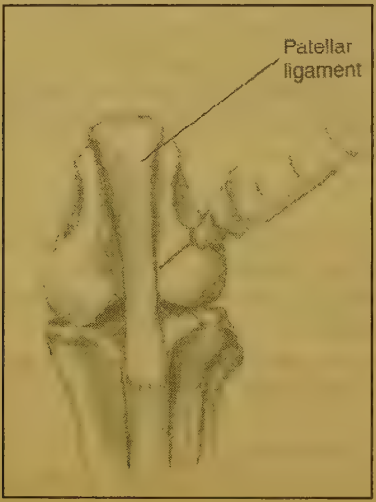

Figure 2. Intra-articular stifle block.

Brachial Plexus Nerve Blocks

Preoperative block (traditional technique):

- For surgery distal to the elbow, a brachial plexus block can be performed preoperatively to block the radial, median, ulnar, musculoskeletal and axillary nerves.
- The needle is inserted into the axillary region, medial to and at the level of the shoulder joint, directed toward the costochondral junction and parallel to the vertebral column.
- Two thirds of the dose is injected after test-aspiration, to ensure the needle is not intravascular or intrathoracic, and the remaining 1/3 is injected as the needle is withdrawn.
- The dose used is 4 mg/kg in dogs and 2 mg/kg in cats of 0.5% bupivicaine, or 8 mg/kg in dogs and 6 mg/kg in cats of 2% lidocaine solution.

Intra-operative block:

- Local anesthetic can be deposited directly around exposed nerves during forelimb amputation.
- Injecting 0.5% bupivicaine (0.2 mL/kg) into the perineurium of the nerves of the brachial plexus 5-10 minutes prior to transection can be efficacious in providing excellent post-operative analgesia.
- 2% lidocaine, or a combination of 2% lidocaine and 0.5% bupivicaine (0.2 mL/kg total volume) can also be used.

Paravertebral brachial plexus block (newer technique):

- The traditional brachial plexus nerve block requires large volumes of local anesthetic to get complete blockade of the plexus, and only blocks the limb distal to the elbow.
- The paravertebral brachial plexus block has been recommended as an alternative for dogs.
- The nerves the C6, C7, C8, and T1 are blocked as close as possible to the intervertebral foramina, instead of in the axillary region.
- The scapula is moved caudally to expose the large transverse process of the sixth cervical vertebra and the first rib
- Ventral branches of C6 and C7 are blocked as they cross the dorsal surface of the transverse process of C6 by inserting a needle dorsal to the process and directing it toward the cranial and then caudal margins of the process
- Ventral branches of C8 and T1 are blocked on the lateral surface of the first rib by directing the needle to the cranial and caudal border of the dorsal part of the first rib, close to the articulation with the vertebra.
- The injection volume is 1–3 mL in dogs or 0.1–0.3 mL in cats of 2% lidocaine or 0.5% bupivicaine, using a 22-gauge, 1-inch needle.
- Both types of blocks can cause blockade of the phrenic nerve, so should not be performed bilaterally.
- Pneumothorax can occur with both blocks.

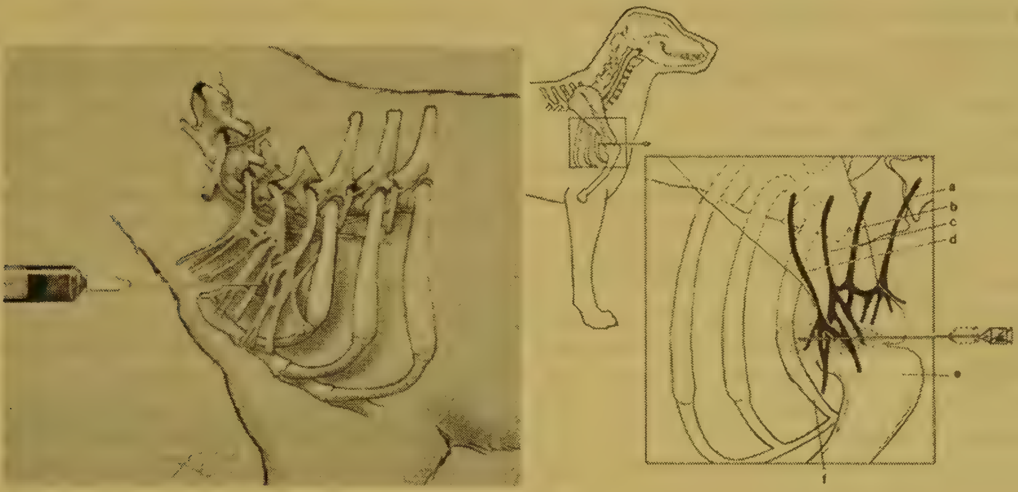

Figure 3. Brachial plexus nerve block techniques.

Onychectomy (Declaw) Nerve Blocks for Cats

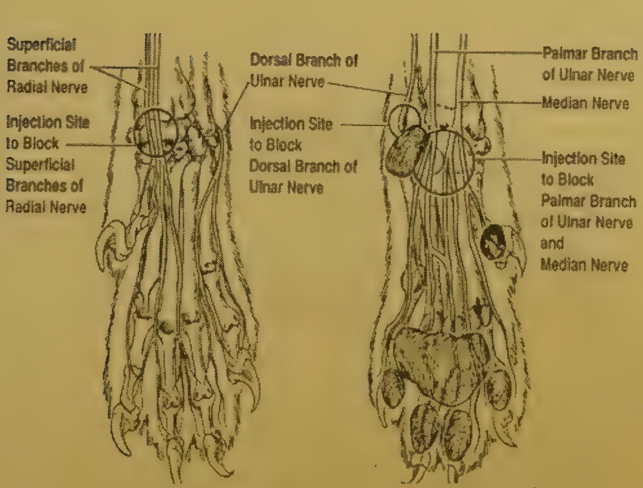
- Blockade of the superficial branches of the radial nerve, the median nerve, and dorsal and palmar branches of the ulnar nerve.
- Effective analgesia for feline onychectomy or orthopedic surgery of the distal extremity.
- 0.5% bupivicaine is the drug of choice for this block due to its long duration of action.
- Inject 0.1 to 0.3 mL of 0.5% bupivicaine (not exceeding the total maximum dosage) at each of three locations:
  - Medial to the accessory carpal pad to block the median nerve and palmar branch of the ulnar nerve.
  - Lateral and proximal to the accessory carpal pad to block the dorsal branch of the ulnar nerve.
  - At the dorsal-medial aspect of the proximal carpus to block the superficial branches of the radial nerve.
  - Alternatively, a simple 'ring' block around the carpus will also block these nerves.

Intravenous Regional (BIER) Nerve Blocks

- Intravenous regional anesthesia (IVRA) is a rapid and reliable method for producing short-term (<1 hour) anesthesia of the distal extremities.
- Minimal systemic absorption of drug, resulting in decreased incidence of toxic side effects.
- The duration of analgesia once the tourniquet has been removed is minimal, and other analgesics should be provided.

Technique

- An IV catheter is placed into a distal vein of a limb (cephalic v., saphenous v.).
- A rubber tourniquet is placed around the limb proximal to the IV catheter.
- Once the tourniquet is secured, **lidocaine**, 2.5–5 mg/kg in dogs, and 2–3 mg/kg in cats, is injected into the catheter.
- Five to10 minutes are required to achieve maximum (surgical) anesthesia, which will last up to 60 minutes.



Superficial Branches of Radial Nerve
Injection Site to Block Superficial Branches of Radial Nerve
Dorsal Branch of Ulnar Nerve
Injection Site to Block Dorsal Branch of Ulnar Nerve
Palmar Branch of Ulnar Nerve
Median Nerve
Injection Site to Block Palmar Branch of Ulnar Nerve and Median Nerve

Figure 4. Onychectomy (declaw) nerve blocks for cats

Figure 5. Intravenous regional or Bier block.

- Sensation will return within 5 to 10 minutes of removing the tourniquet.
- Provides a blood-free surgical site and has been used to inject antibiotics and obtain high tissue concentrations in a distal extremity.
- Limit procedure to ≤ 60 minutes to minimize dcomplications resulting from blood flow deprivation to the limb.

Intercostal Nerve Blocks

- Effective analgesia for thoracotomy or rib fractures.
- The intercostal nerves descend in the intercostal space along the caudal border of each rib, associated with the ventral branches of the intercostal artery and vein.
- The block is performed as dorsally as possible, near the intervertebral foramen.
- The needle is advanced onto the rib, then "walked" caudally until it enters the tissues behind the caudal border of the rib.
- After the syringe is aspirated, the local anesthetic is injected.
- This procedure is repeated to block three intercostal nerves in front of the incision and three caudal to it, in addition to the site of the incision.
- Can be performed immediately after induction of anesthesia for pre-emptive analgesia.
- Articaine may be better to use pre-emptively, when the nerves cannot be visualized, due to its ability to spread through the tissues.
- This block can also be performed prior to closure of the chest wall, from the pleural side.
- Approach from the pleural surface also allows blockade of the dorsal branch of the intercostal nerve, by injecting close to the point at which the nerve exits the spinal canal.
- A total dose of 4 mg/kg of 0.5% bupivicaine (or 4% articaine) in dogs and 2 mg/kg in cats is dividing amongst all the sites.

Maxillary and Mandibular Nerve Blocks

- Excellent analgesia for maxillectomy, mandibulectomy and dental extractions.
- Blocking the maxillary nerve as it exits the infraorbital foramen (A on diagram) will provide analgesia to the canine and incisor teeth in the upper jaw (I avoid this in cats due to proximity of the orbit).
- Blocking the mandibular nerve as it exits the mental foramen (D on diagram) will provide analgesia to the lower incisors.
- To provide analgesia to the entire upper jaw, the maxillary nerve is blocked at the perpendicular portion of the palatine bone, between the maxillary foramen and the foramen rotundum (B on diagram).
    - The needle is inserted through the skin at an angle of 90°, in a medial direction, ventral to the border of the zygomatic arch and approximately 0.5 cm caudal to the lateral canthus.
    - Advance the needle in close proximity to the pterygopalatine fossa.
    - Local anesthetic is administered where the maxillary nerve courses perpendicular to the palatine bone, between the maxillary foramen and the foramen rotundum.
- The mandibular nerve, blocked at the point of entry of the nerve into the mandibular canal at the mandibular foramen, will provide analgesia to the entire lower jaw (E on diagram).
    - The needle is inserted at the lower angle of the jaw, rostral to the angular process.
    - The needle is advanced dorsally, against the medial surface of the ramus of the mandible, to the palpable lip of the mandibular foramen and local anesthetic is injected.
- A 25-gauge 5/8- to 1-inch needle is used and 0.2 mL/kg of 0.5% bupivicaine or 4% articaine is deposited at each site.

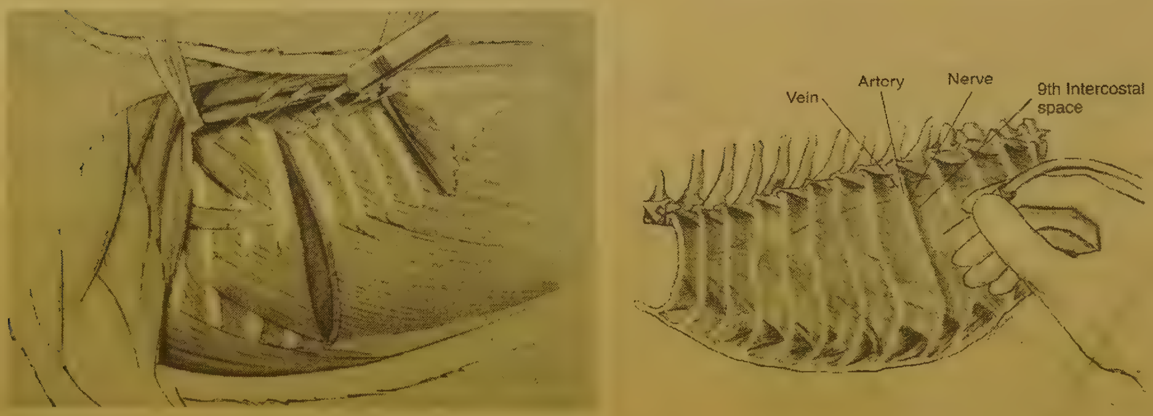


Figure 6. Intercostal nerve blocks.

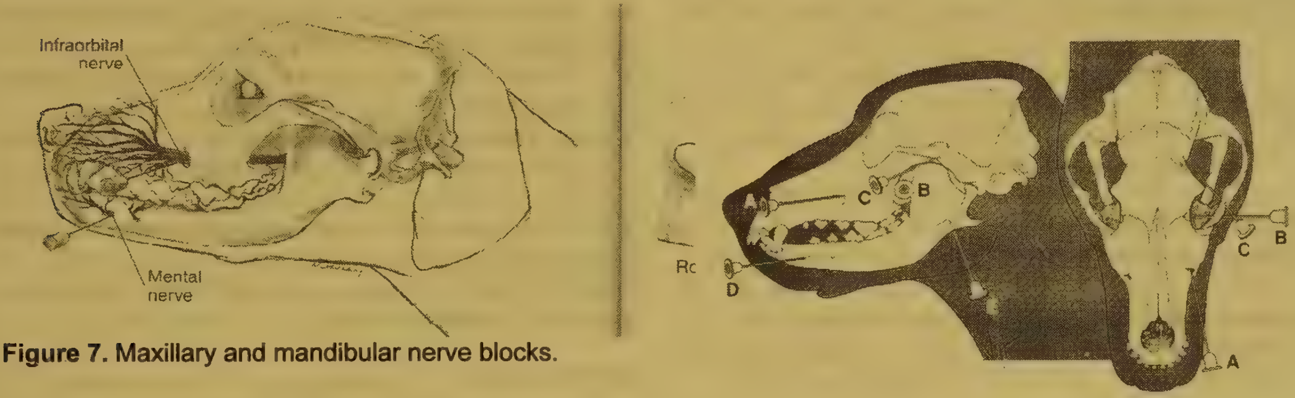

Figure 7. Maxillary and mandibular nerve blocks.

CHALLENGING FELINE ANESTHESIA CASES

Christine Egger, DVM, MVSc, CVA, CVH
Diplomate ACVA
College of Veterinary Medicine
University of Tennessee, Knoxville, TN

HYPERTHYROIDISM

- Prone to dysrhythmias, tachycardia, hypotension, and decreased cardiac output, particularly if concurrent hypertrophic cardiomyopathy
- Make the patient euthyroid prior to anesthesia with methimazole

HYPERTROPHIC CARDIOMYOPATHY (HCM)

- Hypertrophy of cardiac muscle results in impaired myocardial perfusion in the face of increased myocardial oxygen requirements.
- Increased contractility can result in a muscular subaortic stenosis forming during systole, causing a dynamic outflow obstruction and mitral regurgitation.
- Sympathetic nervous system (SNS) stimulation, tachycardia, increased contractility, and increased systemic vascular resistance and afterload should be avoided, as these will reduce cardiac output, concurrently causing an increase in myocardial oxygen demand, predisposing to myocardial ischemia and dysrhythmias.
- If it is possible to delay anesthesia, HCM cats in failure should be stabilized with calcium channel blockers or beta-blockers and pulmonary edema treated.

Anesthetic Management

- Provide supplemental oxygen, if it doesn't stress the cat.
- Avoid SNS stimulation, hypoxemia, hypercarbia, excitement, fear, pain, and stress.
- Avoid hypovolemia and a decrease in venous return; correct fluid deficits prior to general anesthesia.
- If tachycardia is impairing diastolic filling, resulting in hypotension, and no obvious cause of the tachycardia can be found and treated (ie, pain), treat with a beta-blocker (propranolol).
- Avoid hypothermia, as shivering during recovery can increase metabolic oxygen demand by 300%.
- Avoid anticholinergics, but, if necessary, glycopyrrolate is preferred, as it is less likely to cause tachycardia than atropine.
- Avoid xylazine, thiobarbiturates, propofol, and halothane, as these predispose to dysrhythmias and decreased myocardial contractility.
- Avoid ketamine or tiletamine (Telazol®), as both are SNS stimulants.
- Low doses of acepromazine can be used (anti-dysrhythmic).
- Avoid high doses to minimize reduced venous return and cardiac output, and hypothermia.
- Maintain preload with the cautious administration of IV fluids (≤5 mL/kg/hour)
- Monitor CVP and renal output during prolonged anesthesia.
- For hypotension, avoid using a sympathomimetic alpha1-agonist, such as phenylephrine, rather than a beta1-agonist.
- If hypertension occurs, deepen anesthesia with sevoflurane or isoflurane.
- Administer analgesics, mild sedation, and oxygen during recovery.

Premedication

- Midazolam (0.2 mg/kg) or acepromazine (0.01–0.025 mg/kg) combined with butorphanol (0.2–0.4 mg/kg) or hydromorphone (0.05–0.1 mg/kg), IM.
- Administer the opioid first, and the benzodiazepine 10 minutes later, to avoid excitement.
- Low dose medetomidine (2–5 micrograms/kg) can reduce both tachycardia and dynamic outflow obstruction in HCM cats, and is also an anti-dysrhythmic. It may be combined with an opioid.

Induction

- Propofol (3–4 mg/kg IV) if HCM very mild
- Etomidate (1–3 mg/kg IV)
- Propofol or etomidate can be combined with diazepam (0.2 mg/kg, IV) to reduce dosages required for induction.
- Mask with isoflurane or sevoflurane

Maintenance

- Isoflurane or sevoflurane (has less of a tendency to cause tachycardia).

ANESTHESIA FOR CATS WITH ACUTE RENAL FAILURE (ARF), CHRONIC RENAL FAILURE (CRF), URETHRAL OBSTRUCTION, OR RUPTURED BLADDER

Anesthetic Effects on Renal Function

- Most general anesthetic agents decrease glomerular filtration rate (GFR) directly, by causing peripheral vasodilation and decreasing renal blood flow (RBF), or indirectly, by causing decreased stroke volume (SV), heart rate (HR), and cardiac output (CO).
- RBF auto-regulation is maintained at lighter planes of anesthesia (≤ 1 MAC), but not at the deeper levels of anesthesia required for surgery.
- Renal responses to anesthetics also depend on the patient's hydration status.
- Intraoperative renal ischemia can result in ARF post-anesthesia.
- Urine production < 0.5 mL/kg/hour during anesthesia and recovery is considered oliguria, and may be indicative of ARF, secondary to renal ischemia. Renal ischemia can be due to:

Systemic Hypotension

- Uncorrected fluid deficits and inadequate replacement of ongoing losses
- Excessive vasodilation or decreased contractility due to deep anesthesia or high doses of thiopental, propofol, or acepromazine

Renal Vasoconstriction

- Administration of epinephrine or significant (>20%) blood loss can result in severe renal vasoconstriction, increased renal vascular resistance, and up to 40% reduction in RBF.
- Aldosterone, vasopressin, renin, and catecholamines are released with stress and decrease RBF and GFR.

Treatment

- If no cardiac failure or pulmonary edema, a fluid challenge of 10–30 mL/kg of balanced, isotonic crystalloid or 5–10 mL/kg of colloid can be attempted twice.
- Measure CVP before and during fluid challenge.
    - If CVP high, fluid challenge contraindicated
    - If CVP negative, patient is hypovolemic and fluid challenge is indicated.
- If normovolemic, but still oliguric:
    - Dopamine (2–7 µg/kg/min) or dobutamine (5–8 µg/kg/min).
    - If sympathomimetics have been unsuccessful:
        - Lasix (0.5–1.0 mg/kg)
        - Mannitol 0.25–0.5 mg/kg for osmotic diuresis

IMPLICATIONS OF RENAL DISEASE AND ANESTHESIA

Azotemia and Acidosis

- Increased permeability of the blood-brain barrier and sensitivity of the CNS to anesthetics
- Increased fraction of unbound, active drug(s) in the plasma
- Correct the azotemia and acidosis prior to anesthesia with IV fluids, $NaHCO_3$ (0.5–1 mEq/L), and peritoneal or hemodialysis.
- Use lower doses and titrate to effect.

Electrolyte Disturbances

- Hypokalemia (CRF) predisposes to hypotension and dysrhythmias.
- Treat with supplementation prior to anesthesia and avoid placing potassium in anesthesia fluids to avoid rapid administration.
- Hyperkalemia (serum potassium > 6.0 mEq/L) (ARF, urinary obstruction or ruptured bladder), predisposes to:
    - Dysrrhythmias: 1st degree AV block, peaked t waves, loss of P waves, wide QRS complexes, cardiac arrest, death
    - Treat with IV fluids, NaHCO3 (0.5–1.0 mEq/dL, IV), 50% dextrose (2 mL/kg, IV), and regular insulin (0.2 IU/kg, IV; monitor blood glucose), until serum K+ concentration is < 6.0 mEq/dL
- Hypocalcemia can decrease automaticity, contractility, BP, and CO.

Hypoalbuminemia

- Reduction of dosages required of highly protein bound drugs (benzodiazepines, thiopental, or propofol).
- Reduction of the plasma oncotic pressure, resulting in greater chance for pulmonary edema to develop with fluid therapy.

Anemia

- Reduced oxygen carrying capacity, predisposing to hypoxia
- The cardiovascular system may become hyperdynamic in an attempt to maintain oxygen delivery, resulting in hypertension, tachycardia, and increased CO, resulting in decreased cardiac reserve.
- Transfuse prior to surgery if PCV $\leq$ 20%.

CRF or ARF and Anesthesia

- May present polyuric, polydypsic, dehydrated, uremic, acidotic, hypokalemic (CRF), hyperkalemic (ARF), hypoproteinemic, and/or anemic.
- CRF patients may present with hypertension, and may be either hypertensive or severely hypotensive during anesthesia.
- Hypertensive patients should be treated with a calcium channel blocker or ACE inhibitor prior to anesthesia; this may make them more prone to develop hypotension under anesthesia, so provide supplemental fluids and monitor BP.
- .A MAP of > 80 mmHg should be maintained in chronically hypertensive patients during anesthesia to maintain renal perfusion.
- Ketamine, morphine, hydromorphone, and diazepam have active metabolites that are excreted by the kidneys, and should be used cautiously.
- NSAIDS are contraindicated.

Urethral Obstruction or Ruptured Bladder and Anesthesia

- Present with hypovolemia, hyperkalemia, azotemia, acidosis (metabolic and respiratory), hyperphosphatemia, hyperglycemia, hypocalcemia, and hyponatremia.
- The ECG should always be evaluated prior to and during anesthesia:
- ECG changes due to hyperkalemia include small or absent P waves, peaked T waves, prolonged P-R interval, increased duration of QRS, shortened Q-T interval, bradycardia, and sinus arrest; some cats seem to become tachycardic.
- Premature ventricular complexes (PVCs) may also be seen in these patients, particularly if acidotic or hypoxemic.

- If K+ > 7.0 mEq/l, treat until ≤ 6.0 mEq/L prior to anesthesia
- Expect intraoperative changes in serum K^+ with fluid shifts occurring during anesthesia.
- A grossly distended bladder can prevent adequate ventilation, and positive pressure ventilation (PPV) may be required during anesthesia.
- Avoid the rapid drainage of large volumes of peritoneal fluid and urine:
  - Removal of this hydrostatic pressure from the abdomen can allow rapid vasodilation of abdominal vessels and rapid loss of fluid from the inflamed peritoneum resulting in severe hypotension.
  - Sudden loss of severe visceral nociceptive input from a distended bladder may cause a marked decrease in plasma catecholamines, and contribute to cardiovascular collapse.

Anesthetic Management of Patients with Renal Disease

- Always carefully titrate doses to effect.
- Avoid further insult to kidneys due to hypotension, hypovolemia, or production of nephrotoxic metabolites.
- Correct uremia, fluid deficits, and electrolyte and acid-base abnormalities prior to anesthesia
- Pre-anesthesia diuresis for 3 to 4 hours (1.5–3 x maintenance rate) can help prevent intra-operative hypotension, even in normovolemic cats (if cardiac function is normal).
- Intraoperative IV fluid therapy (10 mL/kg/hour).
  - Choice of fluid depends on underlying electrolyte abnormalities, 0.9% saline, Normasol R, or LRS is usually adequate.
  - If hypoproteinemic (< 2 g/dL), administer colloid (Hetastarch or Dextran 70; 5–10 mL/kg) and/or plasma.
- Monitor CVP during anesthesia to help assess blood volume, particularly if there is concurrent cardiac disease.
  - If CVP > 10 cmH_20, decrease or discontinue fluids and administer sympathomimetics and/or diuretics.
- Monitor urine production intraoperatively and postoperatively, if possible, by placement of a urinary catheter.
- Monitor blood pressure during anesthesia, keeping the MAP >60 mmHg, but > 80 mmHg in chronically hypertensive patients.
- Providing adequate analgesia will allow MAC reduction and lower concentrations of isoflurane or sevoflurane.
- Use sympathomimetics to support BP and maintain RBF:
  - Dobutamine: 5–10 μg/kg/min IV
  - Dopamine:
    - 5–10 μg/kg/min IV: Improves CO and RBF
    - > 10 μg/kg/min increases renal vasoconstriction, and decreases RBF
  - Ephedrine: 0.06 mg/kg IV (effects last 20–60 minutes)
- Administer oxygen during recovery, particularly if the patient is anemic and/or hypothermic.
- Administer perioperative analgesia to avoid SNS stimulation and reduced RBF.
- Expect marked diuresis post-surgery and monitor electrolyte and acid-base status closely.

Premedication

- Buprenorphine (0.01 mg/kg) or butorphanol (0.2–0.4 mg/kg) have minimal effects on renal function.
- Morphine has an antidiuretic effect and mu agonist opiates can cause urinary retention, making monitoring of urine output to assess renal function inaccurate.
- Midazolam or diazepam (0.2 mg/kg) has minimal effects on renal function.

Induction

- Propofol (2–4 mg/kg) if normovolemic
- Mask or tank with volatile anesthetic
- Etomidate (1–3 mg/kg, IV)
- Ketamine (5 mg/kg) and diazepam (0.25–0.5 mg/kg) IV, if renal disease is mild to moderate, or if release of the urinary obstruction and subsequent diuresis is probable.

Maintenance

- Isoflurane or sevoflurane

ANESTHESIA FOR HEPATIC LIPIDOSIS OR BILIARY OBSTRUCTION

Feline Hepatic Lipidosis

- Present with dehydration, electrolyte and acid-base abnormalities, coagulopathies, and hypo-albumenemia.
- Severe hepatic lipidosis may result in encephalopathy, requiring lower doses of anesthetic drugs.
- Prolonged recovery has been associated with oxymorphone, hydromorphone, butorphanol, propofol, diazepam, etomidate, and ketamine, so use cautiously.

Biliary Obstruction

- Present with hypovolemia, electrolyte and acid base abnormalities, coagulation abnormalities, hypo-albumenemia, hypoglycemia, and GI ileus (predisposing to regurgitation and aspiration).
- Expect significant postoperative diuresis; careful calculation and replacement of ongoing losses (urine output; serial weights) will maintain renal perfusion.
- Two of the most serious perianesthetic complications in these patients are hypotension and acute renal failure.

Pathophysiology

- Bile duct obstruction induces profound diuresis, as bile salts and products of hepatic metabolism are excreted by the kidney.
- Cardiovascular function is depressed directly by bile salts and other toxins, and responsiveness to angiotensin II and norepinephnine is blunted.
- The combination of hypovolemia and impaired cardiovascular function leads to systemic hypotension and renal ischemia.
- Jaundiced patients, with or without bacterial infection, have elevated concentrations of endotoxin in their blood.
- Endotoxin can cause low-grade intravascular coagulation, renal vasoconstriction, and renal failure.
- Patients with bile peritonitis may be severely hypovolemic, presenting with clinical signs of shock.
- These patients are also very painful, and may require buprenorphine to control pain.

Anesthetic Protocols

- May have decreased hepatic enzyme function, so use drugs that don't rely heavily on hepatic metabolism or that can be reversed
- Avoid morphine as it causes constriction of the sphincter of Oddi, increasing pressure in the common bile duct, potentially causing rupture.
- Benzodiazepines, buprenorphine, and butorphanol are safe and reversible with flumazenil and naloxone.
- Avoid acepromazine because of the potential to cause hypotension and reduced RBF and requirement for hepatic metabolism
- Propofol, if hypovolemia corrected (extra-hepatic sites for metabolism)
- Isoflurane, sevoflurane (minimal hepatic metabolism)

TRANSDERMAL FENTANYL PATCHES AND ALTERNATIVES FOR LONG-TERM ANALGESIA

Christine Egger, DVM, MVSc, CVA, CVH,
Diplomate ACVA
College of Veterinary Medicine
University of Tennessee, Knoxville, TN

Long-term pain management remains a challenge for veterinarians. In addition to economic concerns, owner compliance, off-label use, and efficacy are important in deciding which drugs to use.

OPIOIDS

Transdermal Fentanyl Patches (Duragesic®)

- Produce analgesic plasma concentrations within 12 to 24 hours and 6 to 8 hours of patch placement, in dogs and cats, respectively.
- There is **considerable individual variation in drug levels achieved over time**, making it difficult to predict the adequacy of analgesia.
- Variability can be due to differences in drug delivery and absorption rates, due to alterations in skin temperature, skin blood flow, failure of the patches to stay in place, activity levels of the animals, and individual variability in drug clearance.

Problems with the Transdermal Drug Administration Patch

- Expensive, although generic patches are now available and cost around 40% less
- Often maintain inadequate contact with the skin, resulting in reduced or no uptake of drug
- Fentanyl is a respiratory depressant and can result in hypoxemia and hypercarbia.
- Dysphoria, excessive sedation, ileus, hypothermia, constipation, and decreased appetite can occur.
- If the animal ingests the patch, respiratory depression, excessive sedation, bradycardia and death could occur.
- The potential for accidental exposure of children in the household could be fatal, and because the use of these patches is extra-label, veterinarians are potentially exposed to full liability.
- Fentanyl is a highly addictive opiate and diversion by humans for illicit use results in a significant public health risk.

Buprenorphine (Buprenex®)

- Partial mu agonist with slow onset (20–30 minutes IV, and 30–60 minutes IM), but long duration (6–8 hours).
- Efficacious for mild to moderate pain, particularly if combined with an NSAID.
- Dosage: 0.005—0.02 mg/kg, IM, IV, SQ, orally. 0.005–0.01 mg/kg epidurally.
- Given orally to cats, has 100% bioavailability due to absorption across mucous membranes.

Oral Sustained-Release Morphine

- Absorption is prolonged (6 hours) and bioavailability is low (20%).
- Efficacious in the management of chronic pain in some animals, likely due to the higher levels maintained within the cerebrospinal fluid (CSF)
- The response can be inconsistent, with cats seeming to do better with it than dogs.
- In dogs, the oral sustained release form of morphine is erratically absorbed which may explain the inconsistent responses.
- Dosage: 1.5–3 mg/kg, PO q12h in dogs, and q12–24h in cats

Codeine (Oral)

- Codeine analgesic effects result from metabolism to morphine.
- Its antitussive effects are probably due to direct action on codeine receptors.
- It can be an effective analgesic for mild pain, or as a supplement to a nonsteroidal anti-inflammatory drug (NSAID).
- Oral codeine can be given to cats, but codeine with acetaminophen is **contraindicated.**
- **Dosage:**
  - For mild to moderate acute pain in dogs 0.5–2 mg/kg PO q6–12h
  - In combination with acetaminophen: Using a 60-mg codeine and 300- mg acetaminophen fixed-dose tablet (eg, Tylenol® #4), give 1–2 mg/kg (of the codeine) PO q6–8h.
  - Using codeine alone: 1–4 mg/kg PO q1–6 hours
  - For mild to moderate acute pain in cats: 0.5–2 mg/kg PO q6–12h.

TRAMADOL

- Provides analgesia mainly via by increasing release and decreasing re-uptake of serotonin and norepinephrine in the spinal cord
- Although it is considered a non-opiate, the (+)enantiomer is a weak mu agonist, as is its (+)enantiomer metabolite.
- The (–)enantiomer acts on alpha-2 receptors and serotonin receptors.
- Wide margin of safety in humans, with minimal respiratory, cardiovascular, or GI side effects
- Low abuse potential, is not controlled by the DEA, and lacks pharmacodynamic tolerance

Veterinary Use

- Adverse effects, such as bradycardia, respiratory depression or constipation appear to be less than those seen with common pure mu agonists, such as morphine or hydromorphone.
- Dosage: 1–4 mg/kg, q6h to q8h (dogs and cats seem to vary widely in their response to this drug, so I start at a low dose and work up)
- Duration is around 6–8 hours, but some animals seem to do well on BID treatment.

- Tramadol comes as 50-mg tablets, but can be compounded in a slurry or syrup.
- Comes compounded with codeine for humans, but veterinary experience is limited

NON-STEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDs)

- NSAIDs can be very effective for both acute and chronic pain management.
- Relatively safe for chronic use in dogs, but may not be suitable for chronic use in cats

Advantages to NSAIDs

- Long duration of action
- Anti-inflammatory
- No behavior modifying effects
- No cardiopulmonary depression
- Oral formulations are available
- Not controlled by the DEA.

Toxicity and Side Effects

All NSAIDs have the potential to cause:

- Clotting abnormalities
- GIT toxicity
- Nephrotoxicity
- Cats often have an increased susceptibility to the toxic effects of NSAIDs and these drugs should be used with caution in this species.
- Only ketoprofen and meloxicam are approved for use in cats.

Contraindications

- Renal, liver disease, or GI irritation
- Dehydration, hypovolemia, or hypotension
- Coagulopathies
- If receiving other NSAIDs or corticosteroids
- Pregnant, lactating or breeding animals

KETAMINE

- A noncompetitive antagonist of the N-methyl-D-aspartate (NMDA) receptor, which is associated with the phenomenon of "wind-up" or central hypersensitization of the CNS
- May also act on opioid, serotonin, and norepinephrine receptors to mediate analgesia
- NMDA receptor antagonists have analgesic, anti-allodynic, and anti-hyperalgesic properties.
- It is useful in conditions of neuropathic pain, such as diabetic neuropathy, post-herpetic neuralgia, and interstitial cystitis in people.
- Ketamine, administered as a continuous rate infusion (0.05–0.2 mg/kg loading dose, followed by infusion at 0.5–1 mg/kg/hour), provides very effective analgesia.
- At this dose, the anesthetic effects or CNS excitement effects of ketamine are not usually seen.

TRICYCLIC ANTIDEPRESSANTS (TCAs)

- Useful in the treatment of neuropathic and chronic pain
- Analgesia mediated by inhibition of norepinephrine and serotonin re-uptake in the spinal cord
- Side effects can include sedation, tachycardia, dry mouth, urinary retention, and blurred vision
- Amitriptyline:
    - 1–2 mg/kg PO q12-24h in dogs
    - 2.5–12.5 mg/cat PO once daily
- Clomipramine: 2–4 mg/kg divided BID every 24 hours

GABAPENTIN

- Anticonvulsant that is useful in the treatment of chronic neuropathic pain, and as an adjuvant for acute postoperative pain.
- Premedication with gabapentin has been shown to reduce postoperative analgesic requirements.
- Sensitization of dorsal horn neurons is induced by tissue injury and results in chronic neuropathic pain; gabapentin seems to reduce the hyperexcitability of these neurons.
- Useful adjunct to opioid or NSAID analgesia
- The main side effect is somnolence, and it is excreted unchanged in the urine, so use with caution in patients with renal disease.
- Dosage: 5–25 mg/kg PO q8h

THE PREOPERATIVE PHYSICAL EXAMINATION AND INTERPRETATION OF PREOPERATIVE BLOOD WORK

Karen Faunt, DVM, Diplomate ACVIM
Banfield, The Pet Hospital
Portland, OR

Prior to any anesthetic procedure, the patient's health should be evaluated. This includes conducting a physical examination (PE) prior to induction, completing pre-anesthetic blood work, which should include a complete blood count (CBC) with differential and an internal organ function screen. The CBC with differential and internal organ function screen should be performed within 48 hours prior to anesthetic induction. In addition, the patient's medical record should be thoroughly reviewed, and an IV catheter should be placed. All physical examination findings should be recorded in the medical record, and blood test results reviewed and also recorded. Based on these comprehensive findings, the best anesthesia protocol can then be selected.

CANINE/FELINE PREOPERATIVE PHYSICAL EXAMINATION

The goal of the preoperative physical examination is to determine the patient's health status prior to induction. The conditions to review and evaluate include history and drug therapy, bleeding disorders, hyperthermia, anesthesia problems, shunts, myopathies, and pre-existing organ compromise. One of the two most common times for adverse anesthesia events to occur is during induction. The second is during recovery. Ensuring that the patient receives a thorough physical examination prior to induction will help minimize adverse anesthesia events. If illness is detected upon the physical exam, different best practices (protocols) can be followed that best suit the pet's individual needs. The physical examination can be divided into five categories:

- Assessing capillary refill time and pulse quality,
- Evaluating the mucous membranes for adequate perfusion,
- Auscultating the heart to assess for cardiac health,
- Auscultating the lungs to assess respiratory condition and
- Evaluating the temperature to plan for hypothermia or hyperthermia.

At the beginning of the visit, ensure that an adequate weight has been recorded. During this time, it is beneficial to assess the pet's temperament and disposition. If the patient is a fractious pet, the goal is to immobilize, obtain the necessary blood sample, place the IV catheter and perform the physical examination/patient evaluation immediately. The immobilizing agent should serve as a premed or induction agent.

Capillary Refill Time

A capillary refill time of less than 2 seconds is normal. If the pet has a normal capillary refill time, proceed with the rest of the PE. Anything longer than two seconds is abnormal and subsequently the pet should be evaluated for shock. If the pulse quality is normal, proceed with the rest of the PE. The next part of the PE involves evaluating the femoral pulse rate/heart rate ratio. Any ratio greater than 0.95 is considered normal and the PE can be continued. Ratios less than 0.95 are abnormal and a cardiac protocol should be initiated. Finally, evaluate the pulse quality. In a normal pet, this should be firm and steady. If it is abnormal, again, a cardiac best practice (protocol) should be initiated. Below is a table listing abnormal heart rate values in the awake pet.

Abnormal Heart Rate Values (Awake Pet)		
Species	Greater than	Less than
Small Dog	140	100
Medium Dog	140	80
Large Dog	100	60
Cat	160	120

If the heart rate falls in either the "greater than" or "less than" categories, it is important to follow the cardiac best practice (protocol).

Mucous Membrane Color

Normal mucous membranes are a pink color. If they are pale or have a hemorrhagic appearance, evaluate the hematocrit (HCT) and hemoglobin concentration. If these are normal, proceed with the PE.

Auscultate the Heart

If the heart sounds normal, proceed with the PE. If there is a cardiac murmur, consider the age of the pet. If the pet is young, consider a congenital heart problem or physiologic murmur. Perform an exercise tolerance test. If the murmur is physiologic, the murmur should resolve. If not, consider a cardiac best practice (protocol). If the murmur is an ejection/systolic murmur, consider stenosis and refer to a cardiologist, unless it is an emergency. If a murmur is heard in a mature pet, suspect acquired cardiac disease and proceed to a cardiac best practice.

Auscultate the Lungs

If normal air movement is heard, proceed with the PE. Abnormal sounds may include no movement, noncompliance and/or dry/moist rales. If these sounds are heard, postpone anesthesia if possible and make a clinical diagnosis. Be sure to review the pulmonary protocol before continuing with anesthesia. Also, consider the pet's weight. If the pet is obese, follow a pulmonary best practice (protocol).

Temperature

In cases of hypothermia (body temperature is less than 99°F), give warm 2.5% dextrose in 0.45% sodium chloride IV and warm the pet. If there is no improvement, postpone anesthesia and look for other causes of hypothermia. If the pet has hyperthermia (body temperature of greater than 103°F) check the white blood cell count. If it is elevated, postpone anesthesia if possible. Otherwise, administer 0.9% sodium chloride IV, and IV cefazolin only.

BLOOD WORK EVALUATION

Within 48 hours prior to induction, it is important to review the patient's CBC with differential and internal organ function screen.

Hematocrit, Hemoglobin, and RBC count

Either postpone anesthesia or administer a blood transfusion if the patient has a hematocrit (HCT) of less than 25% and/or a hemoglobin concentration of less than 10. If the HCT is greater than 40% in the cat, and greater than 45% in the dog, review a pre-renal azotemia best practice. If other abnormalities exist, use the appropriate protocol.

Platelets, Clotting Problems

Postpone or transfuse a pet prior to surgery if his/her platelet count is less than 125,000, is von Willebrand's positive, or has some other clotting disorder. Confirm the platelet abnormality/clotting problem by reviewing a fresh blood smear, checking the buccal mucosal bleeding time (BMBT) and evaluating the activated coagulation time (ACT).

WBC Count

If the WBC count is less than 4000, or greater than 15,000, review a blood smear. If neutrophilia with a left shift exists, postpone surgery and make a clinical diagnosis. Otherwise, use an abdominal best practice.

Mean Corpuscular Volume (MCV), Mean Corpuscular Hemoglobin (MCH), and Mean Corpuscular Hemoglobin Concentration (MCHC)

These values will vary depending on the age of the pet. If these values are abnormal, check the pet with pulse oximetry. If oxygenation is low, check liver function. If the MCV is low, consider checking bile acids. Postpone surgery if possible and select a liver protocol to follow.

INTERNAL ORGAN FUNCTION SCREEN

BUN/Creatinine

If the BUN/creatinine is low, review the liver protocol. If it is high, palpate the bladder to check for obstruction. If there is an obstruction, perform a urinalysis (UA) by cystocentesis and follow a post renal protocol. If the urine specific gravity (USG) is high, rehydrate the pet. A high USG for a dog is greater than 1.020, while greater than 1.030 is high for a cat. Address the underlying cause prior to proceeding and consider following a pre-renal azotemia protocol. If the BUN is elevated, but the creatinine is normal, consider gastrointestinal (GI) bleeding. If the USG is low (>1.020 for a dog, >1.030 cat) check other UA parameters. Consider renal disease as a differential diagnosis, and follow a renal best practice.

Calcium

If calcium is elevated, look for renal disease or neoplasia (lymphoma, perianal). If calcium is low, check albumin levels and consider Addison's. In addition, performing an electrocardiogram may be beneficial. If this is normal, proceed.

ALT/Bilirubin/ALKPhos

If these are high, evaluate for liver disease. If the total bilirubin is less than 2.0, check bile acids and evaluate electrolytes. In addition, consider obtaining radiographs and ultrasound. If the electrolytes are abnormal, treat this as a cardiac case. If liver disease is present, avoid using acepromazine and follow a liver best practice.

Albumin/Total Protein

If the total protein is less than 3.5, look for possible causes. Give plasma if possible. Administer diphenhydramine 1.0 mg/lb, with a maximum dose of 50 mg, IM prior to infusion. Wait 30 minutes for effect. Remove acepromazine from the premeds and continue as normal.

Potassium

If potassium levels are high or low, verify the sample value. Look for a potential cause such as urethral blockage, ruptured bladder or compromised renal function. Consider performing an ECG.

Glucose

If glucose levels are less than 100, look for a potential cause. Start 2.5% dextrose in 0.45% sodium chloride IV. If glucose levels are above 200, do a serum fructosamine (SF) test and postpone anesthesia. If SF test positive, follow a diabetic best practice or postpone anesthesia and stabilize the pet.

MANAGEMENT OF THE ANESTHETIC EMERGENCY

Karen Faunt, DVM, Diplomate ACVIM
Banfield, The Pet Hospital
Portland, OR

Emergencies are surgical cases that require anesthesia within 15 minutes to save the patient's life, and though "infrequent patient deaths" might have been considered successful in the past, they can no longer be labeled as quality anesthesia. Our goal should be for the patient's condition to be equal or better than the pet's condition prior to anesthesia. Non-fatal adverse events must be looked at as critically important when determining quality anesthesia, especially when they result in an emergency. Poor perfusion doesn't always result in the patient's death. For example, we want to avoid behavior changes or cortical blindness as a result of a hypoxic event that damages brain tissue during anesthesia.

Outcome analysis over the past years has noted many things:

- Anesthetic reactions are truly very rare.
- Lack of proper monitoring results in the appearance that patients are alive one minute and dead the next.
- Lack of understanding regarding proper drug usage and effects is common.
- Development of unique protocols (ie, bypassing standards) increases morbidity rates and mortality rates.

It is important to not view anesthesia solely as selecting the right drug, but to look at how the pharmacology of the anesthetic agents affects patient perfusion while maintaining a "state of consciousness" that allows a procedure to be performed. If an experienced doctor has the correct drug but the monitoring equipment is not functioning, an adverse anesthesia event or a fatal outcome can still result. Perfusion must be maintained during anesthesia, and as such, patients that are not monitored have higher morbidity and mortality rates.

One of the many things we've learned from outcome analysis is that all drugs are not compatible. Their physiological effects need to be understood well enough to be certain of compatibility. This complex matrix of premeds, induction agents, maintenance agents, and emergency drugs makes well thought out protocols and standards essential.

ANESTHESIA INDUCTION

In general, monitoring patients carefully during the induction phase prevents adverse events. Monitor multiple systems for trends. Continual monitoring and observation should be recorded in the medical record every five to ten minutes until recovery. The primary cause for crisis during or after anesthesia is the failure to notice a problem when it occurs.

If the patient is in shock, anesthesia is contraindicated. If possible, correct shock prior to induction. When correcting shock is not possible (during an emergency), mask induction with sevoflorane may be indicated. Avoid stress when utilizing mask induction; if heart rate increases by 25% or more, allow patient to relax, then administer the appropriate intravenous (IV) induction agent.

EMERGENCIES

Again, emergencies are surgical cases that require anesthesia within 15 minutes to save the patient's life. In event of an emergency when correcting shock is not possible, mask induction with Sevoflorane may be indicated. Avoid stress when utilizing mask induction; if heart rate increases by 25% or more during mask induction, allow patient to relax, and administer appropriate IV induction agent.

True emergencies requiring immediate anesthesia are rare. With true emergency anesthesia, premeds, including butorphanol, may not have had time to take complete effect. Use the minimum amount of drugs for induction and the lowest sevoflorane percent possible for the situation.

Most pets will have a better outcome if stabilized before anesthesia or surgery. A true emergency requiring immediate surgery would include an airway obstruction or acute life-threatening hemorrhage. Gastric dilatation-volvulus (GDV) cases require stabilization and decompression prior to general anesthesia. They don't meet the definition of "emergency" as used in this protocol.

Indicators of an Emergency

Many indicators of an emergency can be noticed if the patient is being monitored on a regular basis. Indicators may include the following:

- Poor or diminishing pulse quality
- Decreased oxygenation (cyanosis may not be present)
- Bradycardia
- VPC

If monitoring End Tidal CO_2 (ET CO_2), patients should be maintained between 35–50 mm Hg. Causes of changes in the exhaled concentrations of carbon dioxide (ET CO_2):

- Increase (>50 ET CO_2) caused by:
    - Hypoventilation
    - Endotracheal tube that is too small (ie, narrowed airway)
    - Malignant hyperthermia
    - Sepsis
    - Rebreathing (CO_2 is not being removed by soda lime)
    - Administration of bicarbonate
    - Insufflation of carbon dioxide during laparoscopy
- Decrease (<35 ET CO_2) caused by:
    - Hyperventilation

- Hypothermia
- Low cardiac output
- Pulmonary embolism
- Accidental disconnection from the anesthetic machine or ET tube extubation
- Cardiac arrest If patient has an ET CO_2 <35 mm Hg, the frequency of ventilation should be decreased. If patient has an ET CO_2 >50 mm Hg, the frequency of ventilation should be increased.

Fluid Therapy

Avoid using fluids containing dextrose in critical cases (cardiac, pulmonary, abdominal), as hyperglycemia is related to an increased risk of re-perfusion injury in the event of cardiac arrest. The 0.9% sodium chloride fluid is also preferred in these cases, as it does not contain additives that will interact with emergency drugs.

Emergency Protocols

1. If a patient's pulse quality or oxygen saturation diminishes, increase delivery of oxygen and fluids. If this fails to improve the patient's condition, give Neo-synephrine, an alpha-1 agonist, intranasally. Since this is a pure alpha-1 adrenergic agent, it causes vasoconstriction to the arterioles without affecting cardiac output.
2. If Neo-synephrine does not result in improved pulse quality and oxygen saturation, administer ephedrine through an IV. Ephedrine indirectly stimulates both alpha-1 and beta-1 agonist activity (causing vasoconstriction and increased cardiac output) by causing the release of norepinephrine. Norepinephrine also affects beta-2 adrenergic receptors, but to a much lesser degree.
3. Give dobutamine, a pure beta-1 agonist, through an IV as a slow drip to increase cardiac output, if the previous steps fail to improve pulse quality and oxygen saturation.
4. As a last step, give epinephrine via IV (it is an agonist to alpha-1s, beta-1s, and beta-2s).

CPR Protocol

Cardiopulmonary arrest (CPA) can be the natural ending of a full life or can result due to trauma or disease states. If CPA is due to a potentially reversible traumatic or medical condition, then prompt application of sound cardiopulmonary resuscitation (CPR) techniques while addressing the underlying cause of the arrest may allow restoration of life signs.

Effective CPR requires a highly trained, efficient and coordinated team, appropriate monitoring devices and medications, and prompt application of CPR techniques. Even with aggressive and effective CPR, survival rates remain low (less than 10%). Controversy exists as to the best CPR techniques and protocol. Therefore, we have combined recommendations from many sources to produce a reasonable CPR process that will benefit the greatest number of patients and utilizes equipment, techniques and medications that should be available in all of our hospitals.

The goal of the following CPR protocol is to provide an outline for closed chest CPR in dogs and cats. This protocol is a template, and to be effective will require training of a team of doctors and nurses that can work together efficiently. The CPR protocol only applies to anesthetic cases once cardiopulmonary arrest is noted.

Recommended team training should include:

- Familiarizing all doctors and paraprofessionals with the protocol.
- Developing a hierarchy of who would be "running the code" (the doctor will usually be running the code but a lead nurse may need to initiate the code). Conduct frequent drills with your team (consider bringing in a stuffed animal as the dummy). This should include the leader assigning duties and directing the code.
- Rotating teams and individual responsibilities during the code drill so that each team member is comfortable doing each job during a code.
- Determine division of labor during a code by the number of team members available. A person may have more than one job responsibility. Assigned roles of responsibility include:
    - Running the code
    - Ventilation
    - Chest compressions (need to rotate the person doing compressions every 3 to 4 minutes to keep up adequate strength of compressions)
    - IV catheter placement, fluid and medication administration
    - Gopher
    - Monitoring
    - Recording

EVIDENCE-BASED BEST PRACTICES PET ANESTHESIA FOR HEALTHY, FRACTIOUS, AND ILL PATIENTS

Will Novak, DVM, Diplomate ABVP
Banfield, The Pet Hospital
Portland, OR

Anesthesia in the pet practice has always been one of the more challenging and complex procedures that a practitioner performs, and yet, it is done every day with hardly a second thought. Even more challenging is the wide variation of anesthesia practices used by different doctors. There is a need to standardize anesthesia protocols for use by general practitioners.

Banfield's anesthesia standards and best practices (protocols) are a result of this thinking. Banfield has the luxury of evaluating more than 125,000 general anesthetic cases a year. By utilizing practice standards and protocols, standardized equipment and ongoing outcome analysis (part of the peer review process—a concept taken from human medicine), a constant process of improvement through learning from ongoing experience occurs.

STANDARDS AND BEST PRACTICES

Anesthesia is often considered to be synonymous with the anesthetic medications used. While the choice of anesthetic agents is important to case outcome, it is only a small portion of complete and successful anesthesia. It is important not to view anesthesia solely as selecting the right drug, but to look at how the pharmacology of the anesthetic agent affects patient perfusion while maintaining a "state of consciousness" that allows a procedure to be performed. To accomplish perfusion-maintenance, other factors besides pharmacology need to be considered. A total system for anesthesia is necessary which results in the development of standards and protocols.

When broadening the discussion of what is included in excellent anesthesia, equipment, patient health status and evaluation (including blood work), drugs and monitoring must all be considered. If an experienced doctor has the correct drug but the monitoring equipment is not functioning, an adverse anesthesia event or a fatal outcome can still result. Perfusion must be maintained during anesthesia, and as such, patients that are not monitored have higher morbidity and mortality rates.

Second, drug selection must be based on a working knowledge of drug interactions and their effects on perfusion. For example, if a patient is sedated with acepromazine, will that affect the safety margin of an alpha-2 agonist? Or, if ketamine is used for an aggressive cat, should atropine be given to prevent bradycardia? One of the many things that has been learned from outcome analysis is that all drugs are not compatible. Their physiological effects need to be understood well enough to be certain of compatibility. This complex matrix of premeds, induction agents, maintenance agents, and emergency drugs makes well thought out protocols and standards essential.

HEALTHY PET BEST PRACTICE

- Perform a complete physical examination and pre-anesthetic blood work prior to any pre-anesthetic or anesthetic drug administration (fractious patients are the exception).
- Pre-anesthesia blood work includes a CBC with differential and internal organ function screen. Perform these tests within 48 hours of anesthetic induction.
- The maximum dose of acepromazine is 1.5 mg.
- The maximum dose of butorphanol is 5 mg. Additional amounts of butorphanol at a pre-anesthetic dose may be given every 1 to 2 hours as needed for post-surgical pain control.
- Premedications administered SQ or IM may need to be diluted before administration to improve drug uptake. Minimum total volume administered should be 0.5 to 3 mL depending on patient size. Dilute with sterile water to final desired volume.
- Acepromazine should be prediluted to 1 mg/mL in a separate vial to allow proper dose administration.
- Allow 30 minutes for premeds to take effect prior to induction of general anesthesia.
- Assess cardiovascular parameters after premeds have taken effect and prior to induction.
- If premeds are given more than three hours before induction, repeat premeds at ½ dose, 30 minutes before induction.
- Administer propofol slowly to effect to minimize adverse cardiovascular effects (average dose is 1 to 2 mg/lb for dogs and 2 to 3 mg/lb for cats). Bradycardia may develop after rapid administration.
- Due to propofol's rapid induction and rapid elimination (approximately three to five minutes) the "overpressure" technique is required for a smooth transition to sevoflurane. Set delivery concentrations at 3%, using an oxygen flow rate of 3 L/minute for the first 3 minutes (3%/3 L/3 min.). For this technique to be effective, the respiratory rate must be near normal or assisted ventilation is used to assure adequate intake and uptake of the inhalation agent. Following the initial three minutes, the oxygen flow is decreased to 1–1.5 L/min., and sevoflurane concentration is adjusted to effect.
- If running sevoflurane at 4% or above, look for system leaks, improper intubation, or inadequate oxygen flow rate.
- Antibiotics other than cefazolin must be administered a minimum of one hour before anesthesia or following complete recovery.

FRACTIOUS PETS

Fractious pets are defined as:

- Needing more than one pet nurse to restrain
- Requiring more than one attempt at a blood draw or jugular stick because of patient movement
- Showing any signs of aggression

Acepromazine in Fractious Pets and Epinephrine Reversal

- Epinephrine (a natural catecholamine) stimulates both alpha and beta receptors. The body can release epinephrine during a stressful event, or in an emergency.
- If an alpha-1 antagonist, such as acepromazine, is administered or on-board (ie, pre-meds), it blocks vasoconstriction of the arterioles by epinephrine through its effect on alpha-1 receptors (a dose-dependent effect).
- Epinephrine can still stimulate beta-receptors, resulting in increased heart rate and contractility (via beta-1), and vasodilatation of the vascular bed in the skeletal muscle (via beta-2). This results in pooling of blood in the vascular beds and inhibits return of blood to the heart, resulting in acute hypovolemic shock. It is therefore important to avoid using acepromazine in the fractious pet protocol.
- If epinephrine reversal is thought to have occurred, give shock doses of fluids to attempt to volume load the patient.

Protocol

- Using Telazol IM early in the course of events helps prevent catecholamine release and thus the adverse physiological events associated with catecholamines.
- Volume-dilute Telazol with sterile water to a volume of 0.5–1 mL for improved absorption.
- The maximum dose of telazol is 100 mg per dose; if after 15–20 minutes effects of medication are not adequate for restraint, the telazol dose can be repeated up to a total dose of 2 mg/lb. Most pets, depending on temperament, will be catatonic in 2 to 3 minutes. This drug will provide 8 to 30 minutes of restraint time. Telazol will lower propofol induction dose by approximately 50%.
- Avoid giving premeds; once Telazol has taken effect, give butorphanol 0.1–0.2 mg/lb SQ/IM.
- The maximum dose of butorphanol is 5 mg; follow up with additional 5 mg every 1 to 2 hours as needed
- Dilute premedications administered SQ or IM to a total volume of 0.5–3 mL depending on the patient's size. Dilute with sterile water. Volume dilution improves drug uptake.
- Antibiotics other than cefazolin must be administered a minimum of one hour prior to anesthesia or following complete recovery.
- Allow 30 minutes for premeds to take effect prior to induction of general anesthesia.
- Assess cardiovascular parameters after premeds have taken effect and prior to induction. ECG is very helpful.
- Assess depth of immobilization; some patients can be intubated without further induction agents.
- Administer propofol slowly to effect to minimize adverse cardiovascular effects. Bradycardia may develop—especially after rapid administration.
- With Telazol, "overpressure" may not be necessary—assess depth of anesthesia prior to utilizing this technique. (Due to propofol's rapid induction and rapid elimination (about a 3- to 5-minute window of duration) the technique of "overpressure" is required to assure a smooth transition to sevoflurane. Set sevoflurane delivery concentrations at three percent using an oxygen flow rate of 3 L/min (3%/3 L/3 min). To be effective, the respiratory rate must be near normal, or use assisted ventilation to assure adequate intake and uptake of the inhalation agent. Following the initial three minutes, decrease oxygen flow to 1–1.5 L/minute and adjust the sevoflurane concentration "to effect.")
- If running sevoflurane 4% or above, look for leaks in the system, improper intubation or inadequate oxygen flow rate.

ILL PETS

Most critically ill pets will not need to be sedated for interosseous catheter placement. If sedation is necessary, use diazepam 0.1 mg/lb IM cats/dogs (maximum dose of 10 mg) plus butorphanol 0.1–0.2 mg/lb (maximum dose of 5 mg) IM. The trochanteric fossa of the femur is the preferred insertion site, but the proximal tibia, or the greater tubercle of the humerus can also be used.

The vaporizer at maintenance levels will normally be set between 2% and 3%. The vaporizer setting and end-tidal sevoflurane concentration are slightly different. Patients that are ill or compromised will often need a vaporizer setting of less than 2%. The goal of gas anesthesia maintenance is to have the patient at a plane of anesthesia that is necessary at any given time. Sevoflurane allows the patient to be taken deeper during the painful part of a surgical procedure, and then taken to a lower plane of anesthesia for closure. The end result is less risk to the patient during anesthesia.

Critically ill patients may be slow to recover from anesthesia. Monitor and document TPR and other vitals frequently and provide supportive care as necessary.

Interosseous catheters may be left in place for up to 72 hours in a critically ill patient. Frequently, they must be pulled within 24 hours if the patient becomes active and bends the needle.

LOOKING FORWARD – LESSONS AND CONCLUSIONS

Will Novak, DVM, Diplomate ABVP
Banfield, The Pet Hospital
Portland, OR

BEST PRACTICES BASED ON OUTCOME ANALYSIS

Quality anesthesia can no longer be defined by "infrequent patient deaths." In an effort to determine what constitutes quality anesthesia, Banfield, The Pet Hospital, has used outcome analysis to evaluate more than 125,000 general anesthetic cases a year. Outcome analysis has indicated that by utilizing practice standards and protocols, standardizing equipment and by implementing a peer review process that promotes continual review of anesthetic practices, a mortality rate of one per 10,000 pets (as close to human quality as possible) is observed. When doctors create unique protocols, the mortality rate increases by four times. In addition to supporting the idea that standardized procedures produce quality anesthesia, outcome analysis has illustrated the following:

- Anesthetic reactions are very rare
- Lack of proper monitoring results in the appearance that patients are alive one minute and dead the next
- Lack of understanding regarding proper drug usage and effects is common
- Development of unique protocols (ie, bypassing standards) increases morbidity rates and mortality rates.

When broadening the discussion of what is included in excellent anesthesia, equipment, patient health status and evaluation (including blood work), drugs and monitoring must all be considered. Regardless of the experience of a doctor, if monitoring equipment is not functioning, an adverse anesthesia event or a fatal outcome can still result. Perfusion must be maintained during anesthesia, and as such, patients that are not monitored have higher morbidity and mortality rates.

PERFUSION BASICS AND PROPER USE OF PREMEDICATION, TRANQUILIZATION, AND IMMOBILIZATION

Adequate perfusion is essential to a successful anesthetic outcome. Evaluating the perfusion of a pet before and during anesthesia is a key component to quality anesthesia management. It is important for the clinician to understand which drugs affect perfusion. Evaluating the perfusion of a patient prior to anesthesia is just one component of the patient evaluation procedure. Within 48 hours prior to anesthetic induction, pre-anesthesia blood work, such as a complete blood count (CBC) with differential and internal organ function screen, should be performed. As always, it is important to review the patient's medical record completely, in addition to performing a thorough physical exam.

After reviewing the results of the CBC with differential and internal organ function screen, as well as conducting a thorough physical exam, determining the most appropriate premedication agents is the next step. Premedications are used to calm the patient, reduce stress, and improve pet handling. Use of proper premedication agents will also decrease the required dose of induction and maintenance agents. The premedication agents used will depend on the health status of each individual patient.

Tranquilization/sedation techniques allow for certain procedures that may include blood collection, otoscopic exams, and may assist in necessary restraint during non-painful procedures. These can also act as anxiolytics. Typically, the patient can still walk, but monitoring the TPR and pulse quality every 15 to 60 minutes is recommended. While tranquilized or sedated, the patient should be under visual observation at all times. The use of an ECG or pulse oximeter can be used at the doctor's discretion. This procedure is recommended for pets over 5 years of age.

Immobilization is typically used for procedures that can be completed in less than ten minutes, are not painful, and do not require general anesthesia. When a patient is immobilized he/she cannot walk and is experiencing a nonsurgical plane of anesthesia. While immobilized, laryngeal and withdrawal reflexes should remain intact. Immobilization techniques may be beneficial for clipping matted hair, radiographs not requiring special positioning, mild ear cleaning, pedicure in aggressive patients, and handling of fractious pets. General anesthesia should be considered in brachycephalic breeds where airway compromise is a concern. Also, pets with excessive pharyngeal folds (Shar pei), or any pet with abnormalities of the pharynx, trachea, larynx and/or esophagus should be maintained under general anesthesia.

SAFE AND EFFECTIVE ANESTHESIA INDUCTION AND MAINTENANCE

Induction methods should facilitate a smooth and calm transition to unconsciousness. However, induction is one of the most common times when adverse anesthesia events occur. In order to prevent adverse events, a complete and deliberate physical examination should be performed on the patient, including a thorough review of the patient's medical record. In addition, a complete CBC with differential, and internal organ function screen should be completed within 48 hours of induction. Ensure that premeds have had 30 minutes to take effect before administering induction agents.

Banfield uses propofol for induction, immobilization and anesthetic maintenance. Telazol can be used when immobilization is necessary and can calm a fractious pet. In addition, this agent can be used as an IV induction agent when lipemia is present. Telazol should not be the first choice with known cardiac disease, but is the safest drug in the Banfield pharmacy for a fractious Pet in the absence of a complete medical history.

Sevoflurane is a newer gas anesthetic maintenance agent. Use of this agent requires a specific sevoflurane vaporizer. Sevoflurane can be used in circle or non-rebreathing circuits. It has similar properties to

Isoflurane, but has some differences. Due to sevoflurane's lower solubility, rapid changes in the depth of anesthesia are possible. This requires close monitoring. With sevoflurane, the return to consciousness is usually rapid. This is especially important in brachycephalic breeds where airway compromise is prevalent. Premedications tend to decrease excitement during recovery.

As always, the three goals of monitoring are to anticipate, recognize and correct complications. Monitoring of the patient's TPR, pulse quality and level of consciousness should be continued until the patient can maintain a sternal position and is fully alert. Anesthetic depth and patient condition are dose dependent. As the anesthetic dose is increased, depth is enhanced and anesthetic safety margins decrease. If uncertain about a patient's anesthetic depth, assume that he/she is too deep. Hypothermia and hyperthermia should also be monitored.

Recovery is also a common time when adverse anesthetic reactions may occur. Continue monitoring TPR, pulse quality and level of consciousness until the patient can maintain a sternal position and is alert. Maintaining a pulse oximeter on the patient will help in this endeavor. Remember to watch for signs of consciousness before removing the endotracheal tube. Signs of increased consciousness include increasing jaw tension, increased swallowing or moving his/her own jaw.

THE PREOPERATIVE PHYSICAL EXAMINTION AND INTERPRETATION OF PREOPERATIVE BLOOD WORK

Prior to any anesthetic procedure, the patient's health should be evaluated. This includes conducting a physical examination (PE) prior to induction, completing pre-anesthetic blood work, which should include a CBC with differential and an internal organ function screen within 48 hours of induction. In addition, the patient's medical record should be thoroughly reviewed and an IV catheter placed. All PE findings should be recorded in the medical record. Based on these comprehensive findings, the best anesthesia protocol can then be selected.

The conditions to review and evaluate during the physical exam include medical history and drug therapy, if the pet has bleeding disorders, hyperthermia, anesthesia problems, shunts, myopathies and pre-existing organ compromise. If illness is detected during the PE, different protocols can be followed that best suit the Pet's individual needs. The physical exam can be divided into the following five categories:

- Assessing capillary refill time and pulse quality
- Evaluating the mucous membranes for adequate perfusion
- Auscultating the heart to assess for cardiac health
- Auscultating the lungs to assess respiratory condition and
- Evaluating the pet's temperature to plan for hyperthermia or hypothermia

BANFIELD EVIDENCE-BASED BEST PRACTICES PET ANESTHESIA FOR HEALTHY, FRACTIOUS, AND ILL PATIENTS

Every pet is unique and some require special consideration prior to anesthesia due to underlying health conditions, breed type (brachycephalic), temperament or organ compromise. Banfield has developed best practices (protocols) as a result of these considerations.

Regardless of the pet's outward appearance, proper evaluation of every pet is necessary prior to anesthesia. A routine CBC with differential and internal organ function screen is performed on each pet. These tests are performed within 48 hours of anesthetic induction.

A few of Banfield's best practices (protocols) include:

- Healthy Pet
- Fractious Pet
- Lipemia
- Abdominal
- Cardiac
- Liver
- Pulmonary
- Emergency Surgery

A fractious pet can be defined as a pet that requires more restraint, a pet requiring more than one attempt at a blood draw or jugular stick because of patient movement, or any pet that shows signs of aggression.

Most critically ill pets will require special treatment that may include interosseous catheter placement, special sedation considerations and extremely close monitoring. Banfield's anesthesia standards and protocols may be adapted to almost any pet with specific health concerns.

MANAGEMENT OF THE ANESTHETIC EMERGENCY

Emergencies are surgical cases that require anesthesia within 15 minutes to save the patient's life. Although outcome analysis has shown that anesthetic reactions are very rare, it is important to work with a team that is prepared for an emergency.

If a patient is in shock, anesthesia is contraindicated. If possible, correct shock prior to induction. If correcting the shock is not possible, mask induction with sevoflurane may be indicated. It is important to minimize stress when utilizing mask induction; if the heart rate increases by 25% or more, allow the patient to relax, then administer the appropriate IV induction agent. Most pets will have a better outcome if stabilized before anesthesia or surgery. In a true emergency, it is important to remember that some premeds used in a healthy pet best practice (protocol) such as butorphanol, may not have had time to take complete effect. Indicators of an emergency include:

- An increase of end tidal CO_2 (>50)
- A decrease of end tidal CO_2 (<35)
- Poor or diminishing pulse quality

- Decreased oxygenation (cyanosis may or may not be present)
- Bradycardia
- VPC

Cardiopulmonary arrest (CPA) can be the natural ending of a full life, or can result due to trauma or disease states. If CPA is due to a potentially reversible traumatic or medical condition, then prompt application of sound cardiopulmonary resuscitation (CPR) techniques, while addressing the underlying cause of the arrest, may allow restoration of life signs.

Effective CPR requires a highly trained, efficient, and coordinated team. This can only result when an effective CPR best practice (protocol) is followed. The goal of Banfield's CPR best practice is to provide an outline for closed chest CPR in dogs and cats. This is a guideline, and to be effective will require training of a team of doctors and nurses on working together efficiently. This protocol only applies to anesthetic cases once cardiopulmonary arrest is noted.

WHAT ARE THOSE MONITORS TELLING YOU?

Lysa Pam Posner, DVM, Diplomate ACVA
College of Veterinary Medicine
North Carolina State University, Raleigh, NC

Modern veterinary practice is filled with colorful, beeping monitors designed to aid in monitoring anesthetized patients. The somewhat mistaken idea is that good monitors equate to greater safety. Expensive equipment is only as good as the person evaluating the information. This article is designed to review the commonly used monitors in veterinary practice and help the practitioner decipher what all the beeping/flashing is about.

ELECTROCARDIOGRAM (ECG)

How Does it Work?

The ECG is a recording of the electrical potentials generated by myocardial cells. The potentials produced are small (low voltage), so using conductive gel lowers the skin's electrical resistance, but artifact and poor signal can be a problem. A lead records the electrical signals of the heart from electrodes which are placed at specific points on the patient's body. When a depolarization wavefront moves toward a positive electrode, it creates a positive deflection on the ECG and when a depolarization wavefront moves away from a positive electrode, it creates a negative deflection on the ECG.

What Does it Tell You?

ECGs are useful to assess the rate, the rhythm, and conduction patterns, of the heart. Each complex can also be inspected to look at individual waves (P, QRS, T) and to see they are normally associated and normal size. Abnormal waves can also be identified; which can aid in clinical diagnoses (eg, ventricular premature contractions [VPC], hyperkalemia, or ST segment depression). Although the ECG is only measuring electrical activity, electrical activity is generally associated with a beating heart (big exception: electromechanical dissociation).

Limitations?

The generation of ECG waves does not give ANY information about cardiac output. Normal rhythms may be associated with poor cardiac output and abnormal rhythms (eg, atrial fibrillation) may be associated with adequate cardiac output. Many ECG monitors auto-calibrate the wave size and therefore wave size may be distorted and misleading. Pulseless electrical activity (previously called electromechanical dissociation; EMD) can produce a fairly normal looking ECG rhythm without a heart beat or circulation.

PULSE OXIMETER

How Does it Work?

A pulse oximeter measures the amount of oxygen that is bound to hemoglobin and is reported as a saturation % (SpO_2). Since hemoglobin with oxygen (HbO_2) and hemoglobin without oxygen (Hb) absorb red and infrared light wavelengths differently, the percentage of one form versus the other can be measured. Hb absorbs more visible red light which is why it appears blue. Complex computer programs help identify pulsatile movement (to differentiate from a vein) and calculate the percent saturation. On room air (21% O_2), most mammals have an SpO_2 between 95% and 100%.

What Does it Tell You?

Pulse oximeters are valuable in they provide information about whether the patient has access to oxygen (eg, O_2 tank turned on), whether the patient is breathing, whether the oxygen is exchanging in the alveoli and whether there is enough cardiac output to get the oxygen peripherally as well as generate a pulse at a peripheral site.

Limitations?

The number generated by a pulse oximeter does NOT provide information about whether there is enough hemoglobin to support the patient, but whether the hemoglobin that is there has oxygen attached to it. For example, the ancient cat with a PCV of 9% (Hb of ~3%) probably does not have enough oxygen carrying capacity to supply the body with sufficient oxygen, but the pulse oximeter could easily read 100% saturated. Since many animals are close to 100% saturated on room air, it can be difficult to assess 100% saturation when higher percentages of oxygen are administered. This means you cannot detect a difference between an arterial O_2 of 100 mmHg or 500 mmHg from a pulse oximeter. Although a pulse is required for a reading, a pulse oximeter does not indicate adequate perfusion. Altered hemoglobin (carboxyhemoglobin or methemoglobin) will alter the accuracy of SpO_2 readings. Methemoglobin will cause the SpO_2 to read 85% and carboxyhemoglobin generally gives a falsely high reading in patients with CO poisoning.

BLOOD PRESSURE

Blood pressure is often used as an indirect measure of cardiac output (CO) and organ perfusion and clinically can be measured in three ways: Doppler, oscillometric, and direct (invasive).

How Does it Work?

Doppler: A Doppler probe can be used by finding an audible peripheral pulse; inflating a sphygmomanometer cuff to occlude flow to that vessel; slowly deflate the cuff until the audible pulse is heard again. The pressure at which the pulse resumes is the systolic pressure. There is some evidence that in cats; blood pressure measured this way is somewhere between mean and systolic pressure.[1]

Oscillometric: Automated blood pressure monitors use a cuff that measures changes in oscillations. The cuff is inflated until the pulse is occluded (no oscillations); the cuff is slowly deflated until the pulse generates oscillations again (that is systolic pressure).

The point of maximal oscillations is the mean blood pressure and the diastolic is usually calculated from the other two values. Anything that can change oscillation (eg, shivering) can negatively affect accuracy.

Direct: For invasive (direct) blood pressure. A catheter is placed into a peripheral artery and connected to a pressure transducer. The transducer can then generate an arterial wave (graphically) and measure systolic, mean and diastolic pressure.

What Does it Tell You?

Depending on the method used, blood pressure monitoring will give you at minimum a systolic blood pressure and often a mean and diastolic blood pressure. Although somewhat oversimplified, systolic pressure is most reflective of cardiac output and diastolic pressure is most reflective of vessel tone. Mean blood pressure is the best indicator of organ (especially renal) perfusion.

Limitations?

Although higher blood pressure is usually associated with increased cardiac output and increased perfusion; that will **NOT** be true with big changes in systemic vascular resistance (SVR). For example, a patient administered medetomidine will initially vasoconstrict and have a decrease in CO. In that patient, the blood pressure will rise with a decrease in CO.

Accuracy is best with direct pressure measurement, followed by Doppler and then oscillometric. Accuracy of an oscillometric is based on many things; appropriate size of cuff, shape of leg, heart rate and rhythm. It is not surprising that accuracy could be different in a Bulldog leg versus a Retriever leg.

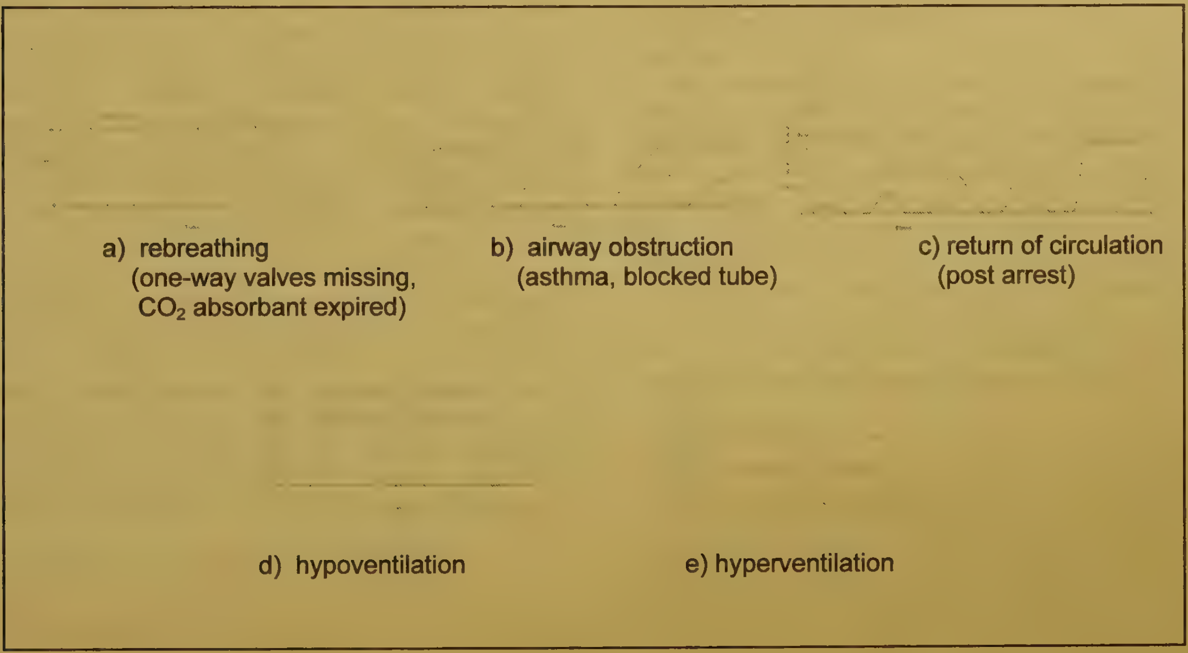
CAPNOGRAPH

How Does it Work?

A capnogram or capnograph is an indirect measure of ventilation. It measures the amount of carbon dioxide (CO_2) in the breath at the end of expiration ($ETCO_2$). Since CO_2 easily moves across the capillaries and alveoli, the assumption is made that the amount of CO_2 at the end of the breath (end-tidal volume) is equivalent to the CO_2 in the blood. In healthy awake animals the difference between the arterial and end-tidal measurements are indeed close (~5 mmHg different). Therefore, capnography allows us to estimate ventilation based on the CO_2 in the breath. The amount of CO_2 in exhaled gas is measured by a comparison with a reference gas for the absorption of infrared light. By plotting the amount of CO_2 exhaled over time, a capnogram can be generated (a graphic representation). The size, upper and lower limits, and shape of the capnogram is quite useful in clinical diagnoses of respiratory as well as mechanical problems.

What Does it Tell You?

Machines that just give an $ETCO_2$ number provide information about ventilation and indirectly cardiac output. If there is insufficient cardiac output to bring the CO_2 to the lungs, then the amount exhaled (even with normal ventilation) will fall. Machines that provide a waveform (capnograph) provide a lot of information about the patient (Figure 1). Inspection of the waveform can give information about the airways (eg, asthma), whether there is a leak in the system (machine or ET cuff), whether there is rebreathing of CO_2 (eg, CO_2 absorbant has expired, or one-way valves are not functioning).



a) rebreathing (one-way valves missing, CO_2 absorbant expired)

b) airway obstruction (asthma, blocked tube)

c) return of circulation (post arrest)

d) hypoventilation

e) hyperventilation

Figure 1. Examples of capnographs.

Capnographs are very useful in arrest situations, as they can indicate successful cardiopulmonary resuscitation (CPR) as well as the return of spontaneous circulation.

Limitations?

Capnography is based on the idea that the end-tidal CO_2 concentration reflects the arterial CO_2 concentration ($PaCO_2$). Although this is true in healthy, awake patients, the difference between the $ETCO_2$ and $PaCO_2$ can become increased with disease (eg, pulmonary thromboembolism), anesthesia, or positioning. The ONLY true was to know arterial CO_2 is to measure it (blood gas).

ANESTHESIA PROTOCOLS FOR CHALLENGING CANINE CASES

Lysa Pam Posner, DVM, DiplomateACVA
College of Veterinary Medicine
North Carolina State University, Raleigh, NC

The variety and complexity of patients seen by veterinarians today are increasing. Many practitioners will be presented with patients for anesthesia that will require them to deviate from their standard anesthetic protocols. This goal of this article is to help the practitioner formulate anesthetic protocols for challenging cases using drugs they likely have in their practice (and/or possibly encourage them to try some new ones).

WHAT MAKES FOR A CHALLENGING CANINE CASE?

Most veterinarians consider a dog a challenge to anesthetize if it has a disease process that might or does interfere with the delivery of anesthesia. Every patient deserves an individual anesthetic protocol, vigilant monitoring, and venous access. However, due to cost and time, many animals are anesthetized in a "routine" way with great success. For those patients who fall outside the routine, it is important to think through the disease process, evaluate the status of the individual patient, have venous access, and monitor the physiologic effect on your patient.

Goal?

The goal of anesthesia is to provide unconsciousness and amnesia while maintaining perfusion of vital organs (brain, kidney, heart, etc.). Adequate perfusion is not just the supply of liquid through the vessels, but providing oxygen and glucose (oxygen delivery). If we recall, energy in the body is supplied by oxidative phosphorylation (aerobic metabolism). The ever important oxygen molecule is necessary for the production of energy in the form of ATP. The ATP is then used to maintain normal physiologic functions (eg, maintaining cellular gradients, protein synthesis, etc.). Cells can produce energy without oxygen (anaerobic metabolism) only on a small scale which is insufficient to maintain an entire body. Furthermore, the by-product (lactate) of anaerobic metabolism contributes to academia (lactic acidosis). Ultimately, without oxygen and the substrates it uses to phosphorylate (glucose, fats) cellular function cannot continue and the body will die. In the author's opinion the majority of patient death under anesthesia is due to the **sequela of poor perfusion and/ or oxygen delivery**.

WHAT ARE SOME THINGS I CAN AFFECT?

Oxygen

Supplemental oxygen is often overlooked as a treatment tool. Remember that room air is ~21%. That means by supplementing oxygen by a face-mask (giving 100% oxygen), you can increase available oxygen four to five times. Normally the VAST majority of oxygen is carried on hemoglobin and only a small portion is dissolved in the plasma (0.3%). However, in anemic animals, if you supply 100% oxygen, the fraction dissolved in the plasma can be a greater percentage (almost 20%) of the total oxygen and provide needed support.

Blood

Anemic patients (packed cell volume [PCV] <20%) who are to be anesthetized should have their oxygen carrying capacity supplemented with red blood cells (whole blood or packed red blood cells) or with hemoglobin (Oxyglobin®) before anesthesia. Anemic patients that are stable awake can quickly become unstable when anesthetized (due to drugs/loss of sympathetic tone/loss of autonomic reflexes).

Volume

Hypovolemic patients should ideally have volume replacement/ resuscitation before anesthesia with crystalloid and/or colloidal solutions. Similar to anemic patients, hypovolemia can be exacerbated under anesthesia due to drugs effects, loss of sympathetic tone, and loss of autonomic reflexes.

Cardiac Output

It is often helpful to identify the cause of low cardiac output (CO). Remember that cardiac output can be influenced by preload (volume returning to the heart), afterload (systemic vascular resistance) and cardiac contractility. Thus it is useful to know from a treatment perspective if cardiac output is being adversely effected because the patient is hypovolemic or inappropriately vasodilated (eg, in shock), or both.

CONSIDERATIONS FOR PARTICULAR CHALLENGING CASES

Aggressive Dog

Aggressive dogs are a danger to everyone in your practice (as well as you) and the sooner they can be chemically restrained, the better it is for everyone. In these dogs it is important that all the medication can be administered with one syringe (ID—intra-dog). Drugs that require large volumes or intravenous (IV) access are not useful. For full chemical restraint, my preference is a mixture of medetomidine and ketamine; medetomidine at 10–20 µg/kg + ketamine 5 mg/kg. Prudence must be used for dogs where alpha-2 agonists are contraindicated (eg, heart disease, hypovolemia).

Cesarean Section

Pregnancy puts a great strain on the dam. Maternal plasma volume almost doubles (a lot of volume for a heart to pump) and decreases in functional residual capacity leaves less respiratory reserve. Most C-section patients are emergent and both the mother and puppies may be compromised. Ideally, puppies should enter the world without any drugs. Unfortunately, almost all drugs that pass the blood brain barrier to anesthetize the dam also cross the placenta and effect the puppy. Therefore, whenever possible, the dam should have no premedicants. The ideal induction agent would provide for a rapid induction and would be easily and quickly metabolized. Although pre-emptive analgesia is always preferred, this is one of the few exceptions where it is prudent to wait until the puppies are delivered to administer an opioid. Some theriogenologists recommend no opioid analgesia so that dam or puppies do not become sedated. Following an abdominal procedure, opioid analgesia is appropriate; however, it might be reasonable to choose a partial agonist to minimize the side effect. NSAIDs are routinely used in the human post delivery period and as long as the dam is clinically healthy and hydrated there is no reason not to do the same.

A large volume of fluid is lost during delivery and many dogs will not drink water during labor. Therefore, all C-section patients should be administered IV crystalloid fluids.

The hypoventilation seen while awake is only exacerbated with anesthesia and dorsal recumbency. These dogs should have their ventilation assisted.

Sample Protocol: IV catheter + fluids; No premedication; Induction with propofol 6 mg/kg IV to effect. Maintenance with isoflurane/ sevoflurane in oxygen (sevoflurane may allow for quicker arousal of puppies). After puppies are delivered the dam should be provided analgesia (eg, buprenorphine 0.02 mg/kg IV, and carprofen).

Drugs to Avoid: Xylazine has been shown to increase the morbidity and mortality of both puppies and dams, likely due to the decrease in cardiac output and decrease uterine blood flow. It is reasonable to avoid other alpha-2 drugs as they would likely produce a similar effect. Human babies are slower to wake up after the moms are administered thiopental (compared with propofol).

Gastric-Dilatation-Volvulus (GDV)

Most dogs with GDV present dehydrated and with poor venous return due to the enlarged stomach. Similarly, they often present hypoventilating due to pressure on the diaphragm. These patients need aggressive fluid therapy and benefit from supplemental oxygen (eg, face-mask). It is important to choose anesthetic drugs that do not worsen the cardiovascular status; that is not decrease cardiac output further either by myocardial depression or vasodilation. After induction of anesthesia, ventilation should be assisted; this can be as sophisticated as a positive pressure ventilator, or from the willing hands of a kennel kid.

Patients who do not respond to aggressive fluid therapy (crystalloids, colloids) may need inotropic support (dopamine or dobutamine) to maintain adequate blood pressure. GDV patients are also often arrhythmic; particularly with ventricular arrhythmias, so lidocaine may be needed for less productive rhythms. (Lidocaine constant rate infusions (CRIs) can be used for adjunctive analgesia as well as antiarrhythmics.)

Sample Protocol: Sedation with hydromorphone 0.01 mg/kg +/- midazolam 0.3 mg/kg IV, IM, SQ (this is often enough to pass a stomach tube for GDV). Induction with midazolam 0.2 mg/kg + propofol 6 mg/kg (to effect). Alternatively, midazolam 0.2 mg/kg + etomidate 2 mg/kg (to effect) can be used. (The midazolam allows for smaller amounts of propofol or etomidate to be used during induction.) Ketamine would be considered an acceptable agent as long as the dog is not severely tachycardic or arrhythmic. Maintenance of anesthesia can be with either isoflurane or sevoflurane. Since both inhalants cause vasodilation, additional analgesia from a CRI of opioid (eg, fentanyl, MLK) or from intermittent boluses can help decrease the amount of inhalant needed. In addition, rehydration, inotropes as needed, and antiarrhythmics as needed.

Drugs to Avoid: Since maintaining blood pressure/ perfusion is vital, drugs that decrease cardiac output or blood pressure should be avoided; alpha-2 agonists (medetomidine), acepromazine, and thiopental.

Brain Tumor

The two major concerns of anesthetizing a patient with a brain tumor are elevated intracranial pressure (ICP) and seizures. Using drugs that are anticonvulsant (eg, benzodiazepines, propofol, thiopental) are wise, as are avoiding drugs that potentially lower the seizure threshold (eg, ketamine, acepromazine?). Similarly, drugs that decrease ICP (thiopental, propofol) should be chosen and drugs that increase ICP (ketamine) should be avoided.

Thiopental and propofol have very favorable CNS pharmacodynamics; they both make the EEG isoelectric (flat), decrease cerebral blood flow, and decrease intracranial pressure. The decrease in EEG waves decreases the glucose and oxygen demands of the brain, and the decreased blood flow decreases ICP. Interestingly, propofol has been shown to maintain cerebral autoregulation during surgery. This fact, the rapid elimination, and lack of accumulation with a constant rate infusion have made propofol my induction drug of choice with CNS disease.

Intracranial pressure can also be affected by CO_2 levels. Elevation of CO_2 (hypoventilation) causes a linear increase in ICP, whereas a decrease in CO_2 will decrease ICP. Anesthesia and some sedative/ analgesics can cause hypoventilation and thus increase ICP (in compromised animals). Therefore. modest hyperventilation ($PaCO_2$ ~35) is recommended for patients with space-occupying lesions while anesthetized.

Sample Protocol: Sedation with butorphanol (0.4 mg/kg). Induction with propofol (6 mg/kg to effect). Maintenance with isoflurane. Hyperventilation while anesthetized. If a painful procedure is planned, a stronger opioid can be used AFTER induction and ventilation is controlled.

Drugs to Avoid: Avoid any drugs that increase ICP (ketamine). Be cautious with drugs that decrease ventilation (increase CO_2) such as pure mu-opioids (eg, morphine, hydromorphone).

Liver Shunt

Dogs with blood shunting around the liver generally have low albumin, low clotting factors, and metabolize drugs more slowly. Often these are young, underweight animals and some present with seizures. When anesthetizing these dogs, it is important to choose drugs that have minimal or alternative liver metabolism (eg, propofol) and avoid long-acting drugs with exclusive liver metabolism (acepromazine). Since albumin levels in these dogs are generally low, drugs that extensively protein bound may have exaggerated effects and oncotic pressure may be low which can lead to hypotension.

Although opioids are liver metabolized, they are good choice in shunt dogs. Opioids provide sedation and analgesia and can be reversed if needed. Midazolam is another good choice as it is water soluble (valium is in propylene glycol), short acting and can also be reversed. Propofol does have some hepatic metabolism, but also has extensive extrahepatic metabolism; as metabolism exceeds hepatic blood flow. In fact, the pharmacokinetics of propofol are virtually unchanged in pigs undergoing liver transplants.

Sample Protocol: Sedation with hydromorphone (0.1 mg/kg). Induction with propofol (6 mg/kg IV to effect). Maintenance with isoflurane. Non-lactate (less for the liver to metabolize) containing fluids. Plasma/ albumin PRN for hypoalbuminemia.

Drugs to Avoid: Acepromazine, thiopental, diazepam

Laryngeal Paralysis

Dogs that present with laryngeal paralysis are often elderly, overweight, and distressed. Before a laryngeal exam, surgery (or referral) can be made the dog must be stabilized. Decreasing the panic and slowing the respiratory rate often helps. Supplemental oxygen can help as long as the face-mask or flow-by does not distress the dog. Dogs that have been working hard to breathe are at risk. They generally have a respiratory acidosis and can suffer respiratory fatigue. For moderately stable dogs, sedation and oxygen therapy will result in a vast improvement. For unstable dogs, they need to be quickly anesthetized, intubated/ tracheostomy and assist their breathing. Use caution with sedative that can increase panting or decrease ventilation (eg, pure mu opioids—morphine, hydromorphone).

Sample Protocol: Sedate with acepromazine, +/- butorphanol 0.2 mg/kg and provide supplemental oxygen. Induction with propofol (6 mg/kg IV to effect) or valium-ketamine. Quickly intubate. Maintain with isoflurane or sevoflurane. Pay attention if the animal is too tired to breathe for itself.

Drugs to Avoid: Avoid pure mu-opioids until airway has been established. Do not mask down with an inhalant (too slow control of airway).

MORPHINE-LIDOCAINE-KETAMINE (MLK)

Lysa Pam Posner, DVM, Diplomate ACVA
College of Veterinary Medicine
North Carolina State University, Raleigh, NC

WHAT IS MLK?

MLK is a solution containing morphine, lidocaine, and ketamine. It is generally delivered as a constant rate infusion (CRI) either during or following surgery.

Morphine is a pure mu-opioid agonist that works by inhibiting ascending nociceptive information by decreasing neurotransmitters (eg, acetylcholine, dopamine, substance P, and norepinephrine).

Lidocaine is a local anesthetic that interrupts the pain pathway by blocking sodium channels and preventing transmission of neuronal impulses.

Ketamine is dissociative anesthetic that disrupts cortical perception of pain and interrupts central sensitization at the level of the dorsal horn of the spinal cord.

WHAT ADVANTAGE DOES IT POSE?

MLK is used to provide balanced analgesia, decrease the amount of inhalant administered, and potentially decrease central sensitization (wind-up). Pain is better controlled when the pain pathway is interrupted/ attenuated in different ways. The three drugs work synergistically and allow for smaller doses of each to be administered. In addition, by providing sedation and analgesia, the combination allows for slower, more comfortable patients in the early postoperative period, particularly with anxious patients or following painful procedures (eg, fracture repair, ear canal ablations, etc). The MAC sparing effects can also provide hemodynamic stability by decreasing the amount of inhalents that are required.

HOW DO I MAKE IT UP AND DELIVER IT?

To quote a non-veterinary proverb: There is more than one way to skin a cat.

The original paper by Muir et al described adding the three drugs to the maintenance fluids and administering at the generic 10 mL/kg/hr while anesthetized. From that paper it is recommended that 10 mg of morphine, 150 mg of lidocaine, and 30 mg of ketamine be added to 500 mL bag of crystalloid fluid and administered at 10 mL/kg/hr. The limitations of this method are that such high fluid rates are rarely used postoperatively, and the fluid rates during anesthesia cannot be altered without altering the drug administration rates. In addition, there is not scientific evidence that the ratio of drugs chosen for that study is ideal and non-alterable. Moderate changes have been suggested and used successfully.

Wetmore suggests that the CRI be administered at 2 mL/kg/hr, thus the solution should be made by adding 60 mg morphine, 750 mg lidocaine, and 150 mg ketamine to a 500 mL bag of fluids. At these concentration and delivery rates: morphine at 4 µg/kg/min (0.24 mg/kg/hr), lidocaine at 50 µg/kg/min (3 mg/kg/hr), ketamine 10 µg/kg/min (0.6 mg/kg/hr).

Alternatively, Stein recommends a solution delivered at 1 mL/kg/hr with a solution made by adding 60 mg morphine, 500 mg lidocaine, and 60 mg ketamine to a 500 mL bag of fluids. Given these concentrations and delivery rate; morphine would be delivered at 2 µg/kg/min (0.12 mg/kg/hr), lidocaine at 17 µg/kg/min (1 mg/kg/hr) and ketamine delivered at 2 µg/kg/min (0.12 mg/kg/hr).

CLINICAL CONCERNS

Clinically, it is important to realize that higher morphine dosing may result in slower recoveries and potentially oversedated patients. The parenteral dose range for morphine is quite large (0.1–0.9 mg/kg q 4–6 hr). Since I generally administer morphine at 0.5 mg/kg q 4–6 hrs to a dog....both protocols above fall into a clinically appropriate dose (one a little higher and one a little lower). Based on toxicity studies, lidocaine administration should not exceed 8 mg/kg q 20 minutes (24 mg/kg/hr). Thus, none of these protocols even approaches toxic levels in a dog. All the ketamine doses are far below the anesthetic dose of ketamine (5 mg/kg) and it is highly unlikely that any behavioral (dissociative) effects would be seen.

CAN I USE IT IN CATS?

All the drugs used in the combination can be safely administered to cats. However, constant rate infusions (CRI) of lidocaine in cats are not recommended as the CV depressive effects are greater than the MAC sparing effects. Therefore, lidocaine can either be omitted or administered at smaller doses.

HOW DO I LOG THE CONTROLLED DRUGS?

Most clinicians find making up 500 mL wasteful in small patients because the morphine has to be associated and signed out with a particular patient. Alternatively, the same ratio of drug can be formulated in smaller quantities (50 mL or 100 mL) based on the size of the patient and how long you expect to deliver the CRI (eg, just during surgery, or over 24 hours).

POSNER'S PREFERENCE?

Analgesic requirement can change vastly from patient to patient and from disease to disease. I prefer to run my opioid CRI independently, so that I may adjust the rate of the opioid as needed. This also makes controlled drug balancing easier.

BUTORPHANOL OR BUPRENORPHINE: WHICH SHOULD I USE?

Lysa Pam Posner, DVM, Diplomate ACVA
College of Veterinary Medicine
North Carolina State University, Raleigh, NC

OPIOIDS

Opioids are the mainstay of analgesia in human and veterinary medicine. There are at least three different types of opioid receptors; mu (μ, OP3), kappa (κ, OP2), and delta (δ, OP1). The previously described sigma (σ) receptor is now considered an NMDA receptor. Presently, only the mu and kappa receptors are clinically manipulated for analgesia. Opioid receptors are widely distributed in the brain, the spinal cord, and peripherally. However, the distribution, density, and even type of receptors vary between species. Binding of opioids to opioid receptors provides analgesia primarily by decreasing neurotransmission (presynaptic inhibition of neurotransmitters, eg, acetylcholine, norepinephrine, substance P, dopamine). This results in hyperpolarization of afferent neurons and thus diminished ascending nociception.

BUTORPHANOL

Butorphanol is a mixed opioid agonist/antagonist. It is an agonist at the kappa receptor and antagonist (really a weak agonist) at the mu receptor. Kappa receptor activation provides mild to moderate analgesia, but less side effects than pure mu opioids. Respiratory and CV depression are minimal; there is less nausea and vomiting, and generally less dysphoria. The analgesic effects of butorphanol have a ceiling effect at ~0.8 mg/kg; where increasing the dose will not increase the opioid effect. Analgesic and sedative effects can be enhanced when given with other CNS depressants (eg, alpha-2 agonists, phenothiazines). Butorphanol is also used as an antitussive.

At clinically relevant doses (0.2–0.4 mg/kg) (IM or IV) butorphanol has a rapid onset of action, but the duration of action in dogs and cats is generally considered less than 1 hour. However, some recent work has shown that individual cats may be provided analgesia for up to 5 hours! Alternatively, butorphanol may also be administered as a constant rate infusion (CRI). Butorphanol administered as a CRI in horses has been shown to be an effective analgesic and actually decreased the duration of hospitalization following colic surgery. There appears to be huge individual patient variability as to potency and duration of action. Therefore, patients administered butorphanol should be routinely assessed for pain.

Behaviorally, cats sedate well with and appear to have a sense of well being following administration of butorphanol.

The effectiveness and duration of oral butorphanol are unknown (unpublished). Some pilot data (also unpublished) indicates the bioavailability at ~10% to 30%.

Butorphanol is a Schedule IV controlled drug, which requires a DEA license as well as controlled access (lock-box) and logbook.

Cost: Butorphanol is supplied as a 1, 2, or 10 mg/mL solution. At clinically relevant doses (0.2 mg/kg of the 10 mg/mL concentration), current (2007—100 mg for ~$50) prices relate to a ~$0.10/kg cost to the veterinarian. Therefore a 0.2 mg/kg dose in a 5-kg cat would be ~$.50 and a 50-kg dog would be ~$5.00.

BUPRENORPHINE

Buprenorphine is a partial mu-agonist and kappa receptor antagonist. It is an interesting drug in that it has a very strong binding affinity, which translates in to a longer duration of action than most other opioids (up to 8 hours). Since it is a partial mu-agonist, buprenorphine has a ceiling effect, so after reaching the ceiling, increasing the dose will not increase the clinical effect. Buprenorphine causes fewer side effects (respiratory, cardiovascular, emesis) than the pure mu-opioids. Side effects may be exacerbated when given with other CNS depressants (eg, alpha-2 agonists, acepromazine).

Buprenorphine can be administered SQ, IM, IV, although time to full effect is generally slower than with other opioids (~30 minutes). Buprenorphine may be administered transmucosally (not orally) in cats due to the high pH (~8.5) of the cat mouth. A dose of 0.1 to 0.2 mg/kg transmucosally will produce similar plasma levels to IV dosing. Recently, buprenorphine patches (transdermal) were assessed, but did not provide analgesia in thermal testing models.

Cats also have favorable behavioral effect with buprenorphine, but rarely become significantly sedated. Interestingly, buprenorphine did not change MAC in cats (which may support that idea that doesn't provide great CNS depression).

There appears to be huge individual patient variability as to potency and duration of action. Therefore patients administered buprenorphine should be routinely assessed for pain.

Buprenorphine is a Schedule III controlled drug, which requires a DEA license as well as controlled access (lockbox) and logbook.

Cost: Buprenorphine is supplied as a 0.3 mg/mL solution. At clinically relevant doses (0.02 mg/kg), current (2007—3 mg for $34) prices relate to a ~$0.20/kg cost to the veterinarian. Therefore, a 5-kg cat dose would be ~$1.00 and a 50-kg dog would be ~$10.00.

BUTORPHANOL + BUPRENORPHINE

Some clinicians administer both drugs in an effort to activate both mu and kappa receptors and to provide both fast onset of action and a long duration of action (Table 1). A recent study in cats, where clinically relevant doses were used, did not show a significant synergistic effect (compared with either drug alone). Interestingly, one could argue that combining the drugs could also provide antagonism at both the mu and kappa receptors.

Table 1. Comparison of Butrophanol and Buprenorphine

	Butorphanol	**Buprenorphine**
Receptor agonist	K-agonist	Mu-agonist
Receptor antagonist	Mu-antagonist	Kappa-antagonist
Dose range	0.1–0.4 mg/kg	0.01-0.02 mg/kg
Time to effect	5–10 minutes	<30 minutes
Duration of action	45 min–5hrs?	Up to 8 hrs
Cost at relevant dose	~$0.10/kg	~ $0.20/kg

EPIDURAL ANESTHESIA AND ANALGESIA: CLINICAL APPLICATION FOR ROUTINE SURGICAL USE

Michael Tillson, DVM, MS, Diplomate ACVS
College of Veterinary Medicine
Auburn University, Auburn, AL

Epidural anesthesia and analgesia is frequently over looked as an adjunct to routine anesthesia and analgesia protocols. Epidurals are initially daunting to perform but with some experience, they can be performed in minutes but veterinary and technical staff in most hospital settings. The primary benefit of epidural anesthesia is the potential to decrease the level of inhalant anesthesia required to maintain the patient while performing a specific surgical procedure. We use epidurals for the majority of rear-limb orthopedic cases, perineal surgery, and caudal abdominal surgery. The addition of morphine to the epidural provides additional analgesia in these cases as well as other cases reaching as far forward as the forelimb.

ANATOMY

The epidural space is the space between the bony spinal column and the spinal cord. It is easily accessed in the caudal aspect of the spinal column and there is minimal risk of injury to the spinal cord at this level. The injection site is between L6-L7 or L7-S1. This is easily identified as the area of the spine between the ilial wings. If you draw a line from one ilial wing to the other and a second line tracing the spinal column, the two lines will bisect over the site for your epidural injection.

EQUIPMENT

Minimal equipment is required for epidurals. A selection of spinal needles should be available; 20g needles of various lengths (1½, 2½, and 3½) would cover more than 95% of small animals. An 18-gauge, 3-inch needle can be used but a 20-gauge 3½-needle can easily substitute. Sterile gloves, a sterile drape, and appropriate epidural agents round out the list.

TECHNIQUE

Aseptic technique is required when performing epidurals. The area around the injection site is clipped (a rough square that is 2 to 4 inches wide in most animals) and prepared with an antiseptic solution. A fenestrated drape (disposable material, sterile surgical towels or plastic adhesive drapes) is placed to cover the area and provide a wider sterile field for the person placing the spinal needle. (Experienced individuals may choose to dispense with the drape as they become confident with the procedure.) The animal is placed in either lateral or sternal recumbency; the positioning is strictly a preference for the individual who is performing the epidural.

Place the fingers of your left hand (non-dominant) on each ilial wings and drop a middle finger directly over the spinal column. Normally, there is a slight depression at this location, representing the space between the spinous processes of L7 and S1. This is the site for initial penetration of the spinal needle.

Insert the spinal needle into the depression and advance it to the bone of the spinal column. Stop at this point and check the orientation of the needle to make sure it is in-line with the spinal column. Slowly walk the needle in cranially or caudally until it "pops" through the interosseous ligament into the spinal canal. The needle is advanced to the ventral aspect of the canal. At this time, you may notice a "tail twitch" in the dog.

Remove the stylet from the spinal needle. Check to see if any cerebrospinal fluid (CSF) escapes from the needle, indicating that you have entered the subarachnoid space. In the event that you have entered the subarachnoid space, you should either 1) reposition the needle in a more caudal intervertebral space or 2) reduce the volume given by 50%. Another technique for checking the needle position is to inject a small amount of air (<3 mL) through the needle. If the needle is in position in the epidural space, there will be no resistance to the injection of the air. If the needle is not in the proper position, there will be resistance to the injection and the plunger of the syringe will bounce back. In this case, replace the stylet and reposition the spinal needle.

Once the spinal needle is properly positioned, slowly inject the desired medication into the epidural space. The direction of injection can be manipulated by turning the needle's bevel in a cranial or caudal direction. For orthopedic surgeries, placing the leg to have surgery in a dependent position for 10 minutes after injection is supposed to concentrate the anesthetic over the nerves to that leg. After you have completed injecting the anesthetic or analgesic into the epidural space, remove the needle and resume preparing the patient for surgery.

FINAL CONSIDERATIONS

Numerous medications have reported for epidural administration. However, there are a few considerations when thinking about epidural anesthesia or analgesia.

- Most references recommend limiting the total volume to 6 mL total. I have given larger volumes without any adverse effects; however, I would recommend heeding this recommendation when beginning to perform epidurals.
- If I am combining an anesthetic and an analgesic in a single injection, I give the analgesic first. The thought process is if I am advancing one of the agents by injecting the second agent, I would prefer to advance the analgesic cranially rather than the anesthetic.
- Whenever possible, use drugs formulated specifically for epidural administration. Giving medications that have preservatives in the formulation have been linked to local inflammation of the spinal cord in humans. While I have not encountered a problem, we use preservative-free epidural preparations for the majority of our epidurals.

- Epidurals can add flexibility to your anesthetic and analgesic protocols. Gaining comfort takes a short period of practice and a proper understanding of the techniques. Try it and you'll be pleased with the results.

Table 1. Epidural Agents

Drug	Dosage Dog (mg/kg)	Dosage Cat (mg/kg)	Onset/ Duration	Comments
Morphine a. Astromorph PF b. Duramorph 0.5 mg/mL	0.1 mg/kg (1 mL/10 lb)	Same	30–60 min/ 12–24 hrs	In early operative period **do not** rely on epidural anesthesia. Premedicate with appropriate complimentary opioid. If CSF, remove and replace or reduce dose by 50% (also reduces duration) Affects only sensory nerves; does not provide significant muscle relaxation
Buprenorphine 0.3 mg/mL	0.003–0.006 mg/kg; add volume up to 0.3 mL/kg	Same	30 min / 12–24 hrs	See above
Lidocaine HCl 2.0% (20 mg/mL)	0.22 mL/kg 1 mL/10 lb	Same	5 min / 60–90 min	Monitor anal tone to assure effectiveness Elevate head first 10 minutes = Place "operated leg" down for 10 minutes Place in dorsal if bilateral or tail procedure Affects motor and sensory nerves
Bupivacaine 0.5% (5 mg/mL)	0.22 mL/kg 1 mL/10 lb	Same	20–30 min/ 4–6 h	May sting in awake or sedated patient Takes a while to see lack of anal tone

INTRODUCTION TO SMALL ANIMAL ANESTHESIA BEST PRACTICES BASED ON OUTCOME ANALYSIS

Lee Tyner, MS, DVM
College of Veterinary Medicine
Mississippi State University, Starkville, MS

Anesthesia in the pet practice has always been one of the more challenging and complex procedures that a practitioner performs, and yet, it is done every day with hardly a second thought. Even more challenging is the wide variation of anesthesia practices used by different doctors. If the question is asked to the many doctors who join Banfield, "Why is there a wide variety of anesthesia practices/protocols being utilized in general practice today?" one common theme comes to the forefront. Every school knows that a wide variety of practice methods currently exist, and as such, they want to expose students to the many variations of practice. This results in no standards of practice for the general practitioner regarding anesthesia. Should the veterinary schools be relied upon to set the standards for general practitioners? The caseloads of most of the veterinary teaching hospitals are referrals, and as such, do not reflect the typical pet practice.

When considering an anesthesia training methodology, a deeper question should be asked which is, "How do you determine quality for anesthesia?" The answer starts with outcome analysis, which helps determine whether the results are better with one method versus another. If practitioners agree that improved case outcomes are a good measure of quality for anesthesia, and a standard method of anesthesia results in improved case outcomes, then anesthesia quality has been improved. Better quality is positive for the profession as a whole.

Banfield's anesthesia standards and protocols are a result of this thinking. The question that I posed in 1998 was, "Can an anesthesia method be developed that would decrease the mortality rate (as well as other adverse case outcomes associated with anesthesia) not only for one hospital, but for hundreds of hospitals?" The challenge forced the question, "Is anesthesia an 'art' or a 'science'?" If it is art, then the mortality rate is based on luck and experience. If it is science, then many aspects of anesthesia should be repeatable with standardized methodologies.

Banfield has the luxury of evaluating more than 125,000 general anesthetic cases a year. By utilizing practice standards and protocols, standardized equipment, and ongoing outcome analysis (the ongoing outcome analysis is part of the peer review process—a concept taken from human medicine), a constant process of improvement through learning from ongoing experience occurs. Peer review, combined with standardized software and equipment, has the benefit of removing many of the variables seen by the profession, and has resulted in marked improvements for Banfield regarding anesthesia case outcomes.

The result of all of this has shown that anesthesia is much more of a science than an art form, therefore forcing practitioners to review their entire approach to anesthesia. Science often requires that old habits of practice change, even if it doesn't feel right, and forces a paradigm shift. Science may require doctors to change, and change is often difficult. This requires practitioners who have a method they would like to stay with, because of habit, or because it just "feels right," to justify with a medical reason, the superiority of the status quo. It is no wonder that many argue against change, but change is upon us.

MEASURING QUALITY ANESTHESIA

Quality anesthesia can be measured by a number of different methods. The first method chosen by Banfield was mortality rate. All anesthesia deaths are taken through the peer review process, and many of these cases also have necropsy results. This provides consistent data on a large enough sample size to identify many patterns that affect mortality. The same factors that affect mortality also affect morbidity; and as such, reducing one will reduce the other.

Research studies regarding anesthesia methodologies and case outcomes in the profession are rare. A study performed with 250 small animal practices in Canada, in which all used isoflurane as the standard, showed a mortality rate of approximately 1 death per 1000 anesthetic procedures. It is a reasonable assumption that in the US, the average small animal veterinary practice is no different, although to my knowledge, no research studies have surfaced. Some have suggested that the mortality rates for general anesthesia in rescue shelters, using injectable anesthesia and minimal monitoring, is as high as 1 per 100. A study by the US Army Veterinary Corps was completed reviewing all deaths and euthanasias of 927 military working dogs from 1993 to 1996, including anesthetic deaths. Anesthetic arrest was noted in 10 of the 927 dogs, or a rate of approximately 1 per 100 patients.

The goal of our protocols is to be as close to human quality as possible (mortality rate of 1 per 10,000). Based on the peer review process, we were able to determine that when the protocols are followed, the mortality rate is approximately 1 per 10,000. These findings were based on case reviews during a time period during which 69,000 procedures were performed. When doctors created unique protocols, the mortality rate increased by 4 times. At a mortality rate of 1 per 10,000 procedures, a doctor averaging 4 general anesthetic procedures per day, and working 220 days per year, would have on average one fatal complication every 11.4 years. It clearly is exciting to have a system that potentially will allow more than 10 years between fatal events.

"Infrequent patient deaths" might have been considered successful in the past but can no longer be labeled as quality anesthesia today. Our goal should be for the patient's condition to be equal or better than the

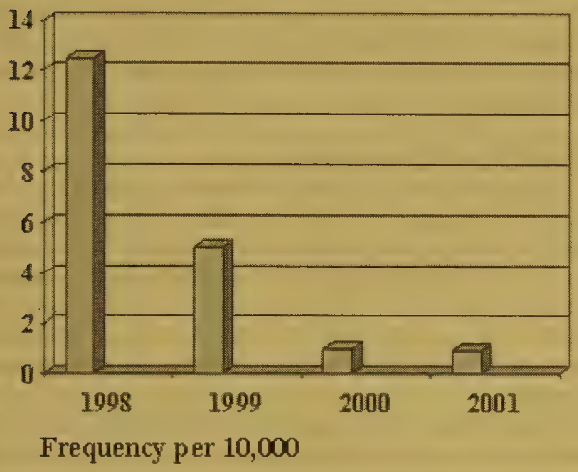

Figure 1. Banfield anesthesia mortality data.

pet's condition prior to anesthesia. Non-fatal adverse events must be considered critically important when determining quality anesthesia. Poor perfusion doesn't always result in patient death. For example, we want to avoid behavior changes or cortical blindness as a result of a hypoxic event that damages brain tissue during anesthesia. While these outcomes are not fatal, they are adverse anesthesia events, nonetheless. How many pets are no longer house broken as a result of brain damage from hypoxia? A great deal of data exists supports the fact that pets with behavior problems are more likely to be euthanized, thus supporting the need for high quality anesthesia.

Outcome analysis over the past years has noted many things:

- Anesthetic reactions are truly very rare.
- Lack of proper monitoring results in the appearance that patients are alive one minute and dead the next.
- Lack of understanding regarding proper drug usage and effects is common.
- Development of unique protocols (ie, bypassing standards) increases morbidity rates and mortality rates.

STANDARDS AND PROTOCOLS

Anesthesia is often considered to be synonymous with the anesthetic medications used. While the choice of anesthetic agents is important to case outcome, it is only a small portion of complete and successful anesthesia. It is important not to view anesthesia solely as selecting the right drug, but to look at how the pharmacology of the anesthetic agents affects patient perfusion while maintaining a "state of consciousness" that allows a procedure to be performed. To accomplish perfusion-maintenance, other factors besides pharmacology need to be considered. A total system for anesthesia is necessary which results in the development of standards and protocols.

When broadening the discussion of what is included in excellent anesthesia, equipment, patient health status and evaluation (including blood work), drugs and monitoring must all be considered. If an experienced doctor has the correct drug but the monitoring equipment is not functioning, an adverse anesthesia event or a fatal outcome can still result. Perfusion must be maintained during anesthesia, and as such, patients that are not monitored have higher morbidity and mortality rates.

Second, drug selection must be based on a working knowledge of drug interactions and their effects on perfusion. For example, if a patient is sedated with acepromazine, will that affect the safety margin of an alpha-2 agonist? Or, if ketamine is used for an aggressive cat, should atropine be given to prevent bradycardia? One of the many things that have been learned from outcome analysis is that all drugs are not compatible. Their physiological effects need to be understood well enough to be certain of compatibility. This complex matrix of premeds, induction agents, maintenance agents and emergency drugs makes well thought out protocols and standards essential.

Clearly, there is more than one way to practice anesthesia. Doctors in any practice can get similar results, provided that all components of the total anesthesia system (ie, equipment, monitoring, standard medications) are consistently utilized, and drug selection and dosages are compatible. Based upon the previously mentioned studies, and Banfield's ongoing outcome analysis, the veterinary profession can improve and obtain better outcomes. The first step in this process is to understand how drugs affect the autonomic nervous system and in turn affect patient perfusion.

PERFUSION BASICS AND PROPER USE OF PREMEDICATION, TRANQUILIZATION, AND IMMOBILIZATION

Lee Tyner, MS, DVM
College of Veterinary Medicine
Mississippi State University, Starkville, MS

In accordance with broadening the practice of quality anesthesia, it is essential to evaluate the patient's health prior to administering premedication, or using tranquilization and/or immobilization techniques. Evaluating the perfusion of a pet before and during anesthesia is a key component to quality anesthesia management.

PERFUSION BASICS

Good perfusion can be defined as having adequate blood flow and volume to push red blood cells to the lungs where oxygen is picked up and then transported to the tissues to ensure that adequate oxygen delivery occurs. In order to maintain perfusion, blood volume, blood pressure, oncotic pressure, and cardiac output must be adequate.

Understanding cardiac output is critical to perfusion. Cardiac output (CO) is the product of heart rate (HR) and stroke volume (SV). Stroke volume depends on venous return (pre-load) and total peripheral resistance, mainly due to arteriole constriction (afterload) and contractility. Upon understanding this relationship, it is possible to understand how tachycardic patients with excessively high heart rates may have a stroke volume that becomes so small that no cardiac output occurs. For example, a cat with a heart rate of 250 beats per minute has literally no cardiac output. If the vagal system is blocked and the heart cannot slow itself, a patient may die from no cardiac output. It is important to remember that preload (venous return) and afterload (peripheral resistance) affect cardiac output as well. If a patient is hypertensive, the cardiac output is decreased because the heart is pumping against the smaller vessel size.

When considering perfusion, blood volume is also critical to maintaining blood flow. The protocols include IV fluids to make certain that the blood vessels are full. As blood vessels are also leaky, oncotic pressure affects perfusion. If the albumin and total protein levels are below normal, pulmonary edema may result during surgery. Patients that develop pulmonary edema during surgery may die several hours postoperatively. This is one of the reasons patients must be monitored for at least 2 hours postoperatively.

Evaluating the perfusion of a patient prior to anesthesia is just one component of the patient evaluation procedure. Within 48 hours prior to anesthetic induction, preanesthesia blood work, such as a complete blood count (CBC) with differential and internal organ function screen, should be performed. As always, it is important to review the patient's medical record completely, in addition to thoroughly evaluating the patient. Confirm that all participating team members are aware of every procedure being performed on the patient. After a complete physical exam, CBC with differential, and internal organ function screen, determine which premedication agents will be the most appropriate.

PREMEDICATION AGENTS

Premedications are used to calm the patient, reduce stress, and improve pet handling. Use of proper premedication agents will also decrease the required dose of induction and maintenance agents. In addition, premedications can improve induction and recovery quality, and some provide analgesia. Premedications are not used to immobilize in order to draw blood or place a catheter.

The premedication agents used will depend on the health status of each individual patient. Some of the more common agents available include acepromazine, butorphanol, diphenhydramine, diazepam, morphine, and a fentanyl patch.

Acepromazine

Acepromazine is a phenothiazine sedative/tranquilizer and an alpha-1 antagonist. As an alpha-1 antagonist, acepromazine results in vasodilatation of arterioles. This action is dose-dependent, so low doses result in slight vasodilatation and a large dose can result in hypovolemic shock. An important point to remember when using this agent is that anything Ace does, fluids can fix.

Butrophanol

Butorphanol is a mixed agonist/antagonist opioid. It can be used for pre-emptive pain management through effects on kappa and sigma receptors. This agent also has analgesic actions at the subcortical and spinal levels providing good visceral analgesia. Little respiratory depression is associated with butorphanol. Since butorphanol also acts as an antagonist to the mu receptors, it can also be used as a reversal agent for pure opioids whose analgesic action is mediated through mu receptors. It is important to remember that because butorphanol is a mixed agonist/antagonist, a ceiling is reached on its analgesic properties, meaning that higher doses do not proportionally equal more pain management. As higher doses are given, the likelihood of adverse effects developing tends to increase. Some of these adverse effects may include aggression, excitement and dysphoria. Therefore, to utilize butorphanol's analgesic properties, but avoid potential adverse effects, the maximum dose a patient should receive, regardless of size, is 5 mg.

Diphenhydramine

Diphenhydramine is an H1 antihistamine. Diphenhydramine can be used as a premed, rather than diazepam or acepromazine, when a patient has received, or is anticipated to receive, a transfusion to help prevent transfusion reactions. Diphenhydramine is preferentially used as the sedative, rather than

Ddazepam or acepromazine, when a patient is undergoing surgery for a mast cell tumor.

Diazepam is a benzodiazepine that produces sedation and skeletal muscle relaxation. It can also be of great benefit in a CNS protocol as it is an anticonvulsant, and will help to prevent seizures in higher risk patients such as the stabilized epileptic requiring a surgical procedure. Midazolam, a shorter acting, water-based benzodiazepine, is substituted for diazepam when it is unavailable. The dose for midazolam is 0.1 mg/lb given subcutaneously (SQ) or intramuscularly (IM).

Morphine

Morphine is a narcotic agent that has good analgesic properties. As a classic analgesic agent, it is an agonist of mu and kappa opioid receptors. Some respiratory depression is associated with morphine, and because it can cause vomiting, and causes histamine release if given intravenously, it should be given intramuscularly only. Morphine is used in standard Banfield Orthopedic and Ear protocols.

Fentanyl Patch

The fentanyl patch is a mu opiate agonist. It has good long-term analgesic properties of approximately 2 to 3 days. This agent can be used in the Orthopedic Protocol in conjunction with morphine. The goal is to use opioids for orthopedic surgery, then to transition the patient from opioids to nonsteroidal anti-inflammatory agents (NSAIAs) within 2 days, and maintain the patient on NSAIAs thereafter as needed. As a transdermal delivery system, it takes approximately 12 hours to take effect; and in some patients, it may take up to 24 hours. The patch is best applied to a shaved area.

TRANQUILIZATION/SEDATION

Determining whether or not a particular patient needs tranquilization/sedation will depend on the procedures being performed, as well as the temperament of the individual patient. Typically, a patient that has been tranquilized or sedated can still walk. Tranquilization/sedation can be used for procedures that may include blood collection, otoscopic exams, or to assist in restraint for nonpainful procedures, and to help decrease anxiety. Prior to administering a tranquilizer/sedative, a complete and deliberate physical examination should be performed. After tranquilization/sedation, it is important to continue monitoring the patient's TPR and pulse quality every 15 to 60 minutes depending on the patient. While the patient is tranquilized/sedated, it should be under visual observation at all times. The depth of tranquilization should be such that endotracheal tube placement is not possible. The use of a heart monitor (ECG) or pulse oximeter can be used at the doctor's discretion. In addition, an intravenous (IV) catheter may be placed. This procedure is recommended for pets over 5 years of age.

AIR TRAVEL

Traveling pets may require tranquilization/sedation. For air travel, Banfield will not prescribe acepromazine or other phenothiazine-type tranquilizers. Phenothiazine derivatives may block alpha-1 adrenergic receptors in the circulatory system, with subsequent vasodilation. This may create susceptibility to hypothermia and an inability to respond to changes in atmospheric pressure and temperature should a pet be in the cargo hold when something goes wrong. Instead of offering a phenothiazine derivative, diphenhydramine is prescribed. This agent will usually cause drowsiness, but does not cause circulatory side effects. Calculate the dose for each pet, 1 mg/lb by mouth, up to a maximum dose of 50 mg. Medication should be given approximately one hour prior to travel. This dose can be repeated every 6 to 8 hours as needed.

Prior to air travel, recommend to the client to acclimate the pet to the pet carrier for several days before the flight. This will decrease the stress that leads to barking, anxiety, and hyperexcitability. Putting a favorite blanket in the carrier and feeding the pet, or offering other treats while in the carrier, helps this process. Finally, recommend non-stop flights to minimize stress to the pet. Pets often get cold or hot while the plane is sitting on the ground.

Ground Travel

Inform clients that oral sedatives have variable effects on pets, and that they are more effective when administered before the pet becomes anxious or excited. Clients will need to closely monitor their pet's reaction to the sedative, and consult with the doctor for dosage adjustments. It is best to start with minimum doses. Recommend giving the agent prior to time of travel, in order to evaluate the pet's response. Also, recommend that the pet travel in a pet carrier whenever possible. Acclimate the pet to the carrier through favorite objects, treats, and feeding.

Oral agents recommended for ground travel include the following:

- Diphenhydramine 1.0 mg/lb PO (maximum dose 50 mg) q 6 to 8 hours
- Diazepam 0.1–0.2 mg/lb PO q 6 to 8 hours
- Acepromazine 0.25–1.0 mg/lb PO q 6 to 8 hours

Immobilization is typically used for procedures that can be completed in less than 10 minutes, are not painful, and do not require general anesthesia. When a patient is immobilized, it cannot walk, and is experiencing a nonsurgical plane of anesthesia. The patient can be aroused with minimal effort and maintains laryngeal and withdrawal reflexes. Immobilization techniques that usually do not require general anesthesia may include:

- Clipping matted hair
- Radiographs not requiring special positioning
- Mild ear cleaning

- Pedicure in aggressive patients
- To enable handling of fractious pets requiring general anesthesia

If a pet is immobilized and the doctor finds the procedure is more extensive than anticipated, general anesthesia may need to be performed. Preanesthesia blood work, IV catheter, and appropriate preanesthesia medications must be completed prior to induction of general anesthesia.

Prior to immobilization, certain requirements should be fulfilled. These include a complete and deliberate physical exam. Monitoring the depth of anesthesia is also important. The depth of anesthesia should be such that endotracheal tube placement is not possible. Continual monitoring and observation should be part of the protocol. Pulse oximetry can be used, and an IV catheter is required for propofol, and at the doctor's discretion for Telazol. The following agents can be used to immobilize patients:

- Telazol 0.5–2.0 mg/lb IM only (use low doses with debilitated patients). Maximum single dose is 100 mg
- Propofol 1.0–4.0 mg/lb IV

Immobilization Considerations in Brachycephalic Breeds

When working with brachycephalic breeds, the potential for apnea resulting in hypoxemia and/or hypercarbia during immobilization with propofol or Telazol is always a possibility, even in apparently healthy pets. Banfield recommends general anesthesia in all patients with the potential for upper airway or pulmonary compromise. These include the following:

- All brachycephalic breeds
- Those with excessive pharyngeal folds such as Shar peis
- Any pet with concern for abnormalities of the pharynx, trachea, larynx, and/or esophagus

This allows for immediate maintenance of a patient airway with an endotracheal tube and ventilation support with 100% oxygen. All general anesthesia prerequisites and monitoring procedures are necessary in these cases. The goal of this recommendation is prevention of unnecessary deaths during immobilization in a high-risk group of patients.

SAFE AND EFFECTIVE ANESTHESIA INDUCTION AND MAINTENANCE

Lee Tyner, MS, DVM
College of Veterinary Medicine
Mississippi State University, Starkville, MS

General anesthesia in the pet practice plays a pivotal role in surgical procedures, radiographs requiring special positioning, invasive diagnostic procedures, and painful procedures. Also, general anesthesia is recommended over immobilization for all brachycephalic breeds.

ANESTHESIA INDUCTION

Induction methods should facilitate a smooth and calm transition to unconsciousness. However, induction is one of the most common times when adverse anesthesia events occur. In order to prevent adverse events, certain requirements should be fulfilled prior to induction. A complete and deliberate physical examination should be performed on the patient, including a thorough review of the patient's medical record.

Ensure that food and water have been withheld for 2 hours. No cases of aspiration have occurred in the practice by using this criterion. Longer periods without food and water (ie, 12 hours) can result in hypoglycemia, especially in pediatric patients. As part of the preanesthetic protocol, a complete blood count (CBC) with differential, and internal organ function screen should be completed within 48 hours prior to induction. An IV catheter should be placed, and an ECG and pulse oximeter can be used for monitoring. Ensure that premeds have had 30 minutes to take effect. If insufficient time is given, a much higher dose of induction agent will be required. Finally, if all preinduction requirements have been fulfilled, ensure that induction doses are administered carefully to effect. Mask or tank induction is not recommended because it is highly stressful causing catecholamine release.

INDUCTION AGENTS

Propofol

Propofol is an alkylphenol that is formulated as an emulsion. The emulsion components are a media that allows bacterial growth; as such, the product has limited shelf life after it has been opened. Propofol is a sedative hypnotic and generally has three main uses that include: use as an induction agent, immobilization/chemical restraint and anesthetic maintenance. As an induction agent, propofol can be used prior to an inhalant and can be given following premeds. As an immobilization/chemical restraint agent, propofol can be used for examinations and diagnostic procedures, for radiography and intradermal allergy testing. Finally, propofol can be used in anesthetic maintenance when intubation is not possible, in status epilepticus that is refractory to Diazepam and as a constant rate infusion at 0.1 to 0.25 mg/lb/minute. The duration of action is five to ten minutes with analgesia only occurring during unconsciousness. Side effects include apnea, cyanosis, and hypotension. Extravasation causes no tissue irritation.

Propofol is a media that allows for bacterial growth, and because it contains no preservatives, its use is limited to one working day. Whenever a bottle is opened, it should be thrown away at the end of the day. This product is not designed for refrigeration or freezing. Be sure to wipe the stopper with alcohol, following sterile technique, when drawing up a dose of this induction agent.

It is recommended to give one-quarter to one-third of the calculated dose as a bolus, assess the patient, and give the rest as needed to allow for intubation. The average dose of propofol following premedication is 1.0–3.0 mg/lb and 2.0–4.0 mg/lb if no premedication is administered. Cats often require closer to 3.0 mg/lb even with premedication.

Telazol (Zolazepam and Tiletamine)

Telazol is similar to diazepam and ketamine, but has greater synergism. Major uses include immobilization in routine cases, calming a fractious pet, intravenous (IV) induction when lipemia is present and induction for the Ear protocol if no other health problems are present. Zolazepam is a diazepinone minor tranquilizer. Telazol should not be the first choice with known cardiac disease, but is the safest drug in the Banfield pharmacy for a fractious pet in the absence of a complete medical history.

INTUBATION

Prior to intubation, it is always important to have all proper equipment ready, including various sizes of endotracheal (ET) tubes, topical Lidocaine (viscous), gauze and KY jelly. Use of a laryngoscope is always recommended. Choose an appropriately sized ET tube. Generally, the largest tube that will fit easily without trauma is recommended. Be sure that cuffs are tested for integrity before use. Measure the ET tube so that it will reach only to the thoracic inlet. Mark this location on the tube and tie gauze around it at this spot. If using a stylet, ensure that it does not protrude beyond the end of the ET tube. Lubricate the tube with KY jelly or its equivalent. While supporting the patient in sternal recumbency, gently pull the tongue out. For cats, it may be helpful to swab the vocal folds with Lidocaine, which helps to prevent laryngospasm. Laryngospasm is most likely to occur if forced intubation is attempted while the cat is too lightly anesthetized. It is important to remember that severe laryngospasm can kill. If a patient laryngospasms, place a large gauge needle into the trachea and administer pure oxygen until swelling decreases. Using a laryngoscope to visualize the laryngeal folds, place the ET tube into the trachea. Once the tube is in the trachea, secure it around the patient's upper nose or the back of the head, using the gauze strip. Listen for leaks before inflating the ET tube. It the tube is a tight fit, little to no cuff inflation is necessary. Using airway pressure as a guide, only inflate to prevent a leak to a pressure of approximately 20 cm water.

The cuff at the end of the ET tube is designed to close the air space between the outer walls of the tube and the inner walls of the trachea. This prevents the patient from breathing around the tube, or, receiving an inadequate or inappropriate amount of oxygen and anesthesia. Before using the ET tube, be sure to check the cuff for leaks. This can be accomplished by gently inflating the cuff with a syringe of air. (Over-inflation will destroy the cuff.) Watch the balloon inflate. Gently squeeze the balloon to determine if there are any leaks. Once it has been confirmed that there are no leaks, deflate the cuff by reattaching the syringe and withdrawing the air. The cuff should be deflated before intubation.

ANESTHESIA MAINTENANCE AND MONITORING

Sevoflurane

Sevoflurane is a newer gas anesthetic maintenance agent. Use of this agent requires a specific sevoflurane vaporizer. Sevoflurane can be used in circle or non-rebreating circuits. It has similar properties to Isoflurane with some differences: .

- It has a lower solubility than Isoflurane, which allows for rapid changes in the depth of anesthesia. Due to this potential of rapid change in depth, it allows for more precise control, but also requires closer monitoring because it is easier to have a patient extremely deep within a few minutes.
- At maintenance levels, the vaporizer will normally be set to between two and three percent. The vaporizer setting and end-tidal sevoflurane concentration are slightly different. Patients that are ill or compromised will often need a vaporizer setting of less than two percent.

Return to full consciousness is usually rapid. This is especially important in brachycephalic breeds where airway compromise is prevalent. Premedications tend to decrease excitement during recovery.

Oxygen Flow Rates During Anesthesia

When using the Unilimb (Universal F Circuit) anesthesia tubing (a re-breathing system), current anesthesia protocols call for oxygen flow rates of three liters/minute during the first three minutes of anesthesia with the sevoflurane level at 3% when pets are induced with propofol. This results in a smooth transition from induction to maintenance anesthesia. This is not done with a Telazol induction. Following the transition phase, oxygen flow rates are decreased to 1.0–1.5 liters/minute. In the majority of patients, higher oxygen flow rates are not necessary to maintain oxygen saturation of greater than 94 percent. Higher oxygen flow rates vaporize sevoflurane faster, thus increasing the cost of anesthesia.

Assisted Ventilation

When assisted ventilation is necessary, it is important to deliver the correct inspiratory pressure to avoid adverse pulmonary function or complications.

- 12 to 15 cm water for small pets and pets with chronic pulmonary disease,
- 20 cm water for medium to large pets,
- 25 cm water may be required for giant pets.

Ventilation should be delivered in a manner similar to normal respiration, avoid holding inspiratory pressure. The manometer should return to zero between breaths when no pressure is on the bag. The pressure relief "pop-off" valve should be open when not assisting ventilation and should only be closed enough to reach desired positive pressure during assisted ventilation.

Monitoring

The importance of monitoring patients during anesthesia is to evaluate tissue perfusion. Anesthetics depress autonomic nervous system function, which is what maintains perfusion. Monitor multiple systems for trends. The primary cause for crisis during or after anesthesia is the failure to notice a problem when it occurs. The three goals of monitoring are to anticipate, recognize and correct complications. The patient should be continuously monitored until a sternal position can be maintained.

Anesthetic depth and patient condition are dose dependent. As the anesthetic dose is increased, depth is enhanced and anesthetic safety margins decrease. Anesthetic depth is determined by skeletal muscle tone, selected reflexes (including jaw tone and withdrawal) and corneal position. Direct response to surgical stimulation is the most reliable indicator of determining depth of anesthesia. If uncertain about a patient's anesthetic depth, assume that he/she is too deep. If monitoring the end tidal CO_2 (ET CO_2) patients should be maintained between 35 and 50 mm Hg.

Hypothermia (body temp below 98°F, 37°C) is common after 30 minutes of surgery. Hypothermia enhances depression, prolongs recovery and increases stress. Signs of hypothermia include cyanosis, arrhythmias, cool extremities, decreased respiratory rate and shivering. For every degree body temperature falls below 100°F, the anesthesia requirements decrease by approximately 5%.

It is best to prevent heat loss with pads, warm IV fluids, using warm surgical scrub and minimal amount of alcohol during the surgical prep. These methods will not decrease body temperature, but will slow heat loss. Warming patients can be accomplished by two methods that include surrounding the patient with warm air and warming the inspired air. When surrounding the patient with warm air, use a trash bag with a hole cut in the bottom of the bag for the head to protrude. In the open end of the bag, circulate warm air with a hair dryer. This provides warm air in contact with enough surface area to warm the patient. When warming the inspired air, use a warm water trap added to the anesthesia machine, or by shining a light bulb on the soda lime canister. Care must be taken to prevent the temperature of the soda lime from exceeding 100°F; place thermometer strips on the canister in various locations to monitor canister temperature.

Recovery

Along with induction, recovery is another common time for adverse anesthetic reactions to occur. It is important to continue monitoring TPR and pulse quality until the patient is able to sit sternally and is fully alert. Maintain a pulse oximeter on the patient until he/she is fully awake and ensure that monitoring of patient is documented in the medical record. Deflate the cuff on the ET tube at the first sign of increased consciousness. Signs of increased consciousness include increasing jaw tension, and increased swallowing. As the patient begins to swallow or move the jaw, remove the ET tube. Once the patient is sternal and normothermic, the Pet may be moved to a kennel. Fractious or dysphoric dogs can be given 0.025 mg/lb Acepromazine IV slowly (maximum dose is 1.5 mg) to effect for rough recovery. This is given only during recovery. Check for hypothermia and hypoglycemia if recovery appears to be slower than normal. Correct these conditions if present.

EVALUATION OF THE EFFICACY OF A SYNTHETIC PHEROMONE ANALOGUE IN THE TREATMENT OF STORM PHOBIA IN DOGS: A PILOT STUDY

Subjects and Methods

Twelve storm-phobic dogs, two neutered males and ten neutered females, were treated with a combination of dog-appeasing pheromone (DAP) and behavior modification in an open, pilot study of this treatment protocol. Patients were recruited from dogs owned by the faculty, staff and students of the University of Georgia College of Veterinary Medicine. To be included in the study, dogs had to be at least 6 months of age, not have any history of aggression, health problems or other significant behavior problems. They had to have exhibited at least one of the following behaviors on three different occasions during storms: elimination, excess salivation, excess vocalization, destructiveness, hiding, pacing, panting, self-trauma, staying near the owner, or trembling. A Storm Phobia Assessment questionnaire (SPA) that has been used in previous research on the treatment of storm phobia[1] was also completed for each patient. Dogs with a score of 10 or less were not included, as dogs with this score were considered to have very mild storm phobia that owners are not likely to present as a problem. Dogs with a score greater than 30 were also not included, as this constitutes dogs with a very severe problem that are likely to require medication in addition to more conservative treatment. Dogs with scores from 11 to 30 were included.

Treatment consisted of providing DAP as a continuous diffuser in the location where the dog spent most of its time and desensitization and counter-conditioning with storm CDs for 10 to 15 minutes a minimum of 3 days a week. Owners were also instructed to neither punish nor comfort their dog if it acted afraid during storms.

All participants were provided with diaries in which to record whether or not there were any storms that day, the specific characteristics of the storm (eg, thunder, lightning, rain, strong winds), the dog's response to the storm, and whether or not they checked the diffuser to confirm that it still had liquid in it and was plugged in. Dogs were treated for a minimum of four storms. At an exit visit that occurred after a minimum of four storms, a second SPA questionnaire was completed by the owner. In addition, owners completed global assessment forms. Dogs experienced 4 to 12 weather events during the course of treatment.

RESULTS

Nine dogs showed decreased SPA scores ranging from 5% to 75%. Two dogs, one female and one male, had increased SPA scores, while one dog showed no change. The Wilcoxon Signed Ranks Test comparing pre- and post-treatment scores was significant ($P = 0.018$). The mean percent decrease in SPA score was 25%.

The two dogs that had an increased SPA score exhibited increases of 16% and 18%. The two dogs with the largest decrease in score exhibited decreases of 75% and 69%. In their global assessment, owners had a choice of Worse, Unchanged, Somewhat Better, Substantially Better but Not Resolved or Resolved. No owners rated their dogs as Worse or Resolved. Five owners rated their dogs as Somewhat Better, four as Substantially Better but Not Resolved, while three owners rated their dogs as Unchanged. Thus, 9 out of 12, or 75% of the owners believed that their dogs had shown some degree of a positive response during treatment. There was no relationship between the number of weather events experienced during treatment and improvement. There was not a significant relationship between beginning SPA score and change in SPA score. The three dogs with the greatest decrease in their SPA scores had pre-treatment SPA scores of 23, 24, and 29. The three dogs that had no change or an increase in their SPA had pre-treatment SPA scores of 17, 21, and 25

CONCLUSION

DAP may facilitate improvement in symptoms of storm phobia. Since this was a pilot study and the dogs also received some behavior modification, further research is needed to confirm this.

PRACTICAL APPROACH TO THE TREATMENT OF SEPARATION ANXIETY IN DOGS

Debra F. Horwitz DVM, Diplomate ACVB
Veterinary Behavior Consultations
St. Louis, MO

Because domestic dogs usually consider the human family to be their social group, they become bonded to family members. When separated from family members, dogs may experience distress and engage in problem behaviors related to the anxiety of separation. These behaviors include destruction, vocalization, elimination of urine and/or stool, anorexia, drooling, attempts at escape, and/or behavioral depression. Treatment protocols include independence training, habituation, counter-conditioning and desensitization to owner departure and absence, pheromones. and pharmacological intervention.

HISTORY TAKING

Separation anxiety seems to be quite prevalent in the companion dog population. Dogs that are adopted as adults from humane shelters appear to be over-represented in case loads of dogs diagnosed with separation anxiety. The problem behavior(s) cited are destruction, vocalization, and/or elimination in the house while the owners are gone.

The dog may engage in only one of these behaviors or all three or other problem behaviors may be present. Geriatric dogs are more commonly seen for the behavioral complaint of separation-related anxiety when compared with younger dogs.

Diagnosis of separation anxiety should not be made solely on the basis of destruction or vocalization when the dog is left alone; in many cases signs of increased attachment to the owner and distress as they get ready to depart is noted. Dogs with separation-related anxiety often follow their owners while they get ready to leave or keep them within their field of vision. Dogs may exhibit anxiety by whining, panting or pacing while others become immobile, as the owner gets ready to depart. Most dogs engage in the separation-related behaviors within 30 minutes of owner departure. Self-mutilation, excessive licking, and vomiting or diarrhea can also occur as symptoms of separation distress. While most of the problem behavior occurs shortly after owner departure, some dogs may cycle through periods of re-arousal perhaps brought on by outside stimulus.

An additional component in the history of separation anxiety dogs is their excitement when their owner returns. Their greeting behavior is often exuberant and prolonged. In addition, dogs with separation anxiety are at risk for noise phobias and dogs with noise phobias appear to be at risk for separation anxiety.

DIAGNOSIS

Before establishing a diagnosis of separation anxiety, other causes of house soiling, destruction, and vocalization must be ruled out. Differential diagnoses for dogs that eliminate when left alone include medical causes of house soiling, inadequate house-training techniques, marking, and prolonged periods without access to appropriate elimination locations. When dogs are destructive or barking, alternate explanations including young, energetic dogs with limited exercise or play, external stimuli, and territorial displays should be explored. Destruction may be a component in noise phobias such as thunderstorm phobias. Geriatric dogs may be experiencing changes in cognition and should show other signs of cognitive decline such as wandering, loss of house training, disturbances in sleep/wake cycles, and other symptoms that have been associated with Cognitive Dysfunction Syndrome. Some dogs may be distressed when the owner is gone due to fears, phobias or anxieties about events that occur in the owner's absence such as storms or other loud noises. If none of these apply, then a diagnosis of separation-related anxiety is appropriate. If the history is not clear, then owner journals, audio and/or video tapings, and appropriate medical testing may be helpful in establishing a diagnosis. In some situations, more than one dog is showing anxiety and distress and all patients must be treated.

TREATMENT

Standard behavior modification treatment plans generally have the following components:

Owner Education

Owners need to be counseled that the behavior is anxiety based, not spiteful.

Restructuring the Pet–Owner Relationship

Owners should be given tools to make the dog less attached and their interactions with their pet more focused and structured. Ignoring attention-seeking behaviors, teaching sit/stay, decreasing following behaviors and earning attention by performing a task first are commonly recommended. A predictable routine for exercise, play and attention should be established and followed. Teaching the dog to settle and relax in a set location or on a bed or mat can be useful to teach the dog how to be calm on cue. Once learned, this can be helpful to calm the dog before owner departure.

Departures and Returning: Habituation to the Pre-departure Cues, and Changing the Leaving and Return Routine

Animals quickly learn to associate various departure cues (getting keys, briefcase, lunch, etc.) with the owner leaving and may become anxious when these are performed. The goal is to reduce the predictive value and thus anxiety producing quality of the steps in the owner's departure routine. In order to uncouple these cues from actual departures, the owner is asked to perform them without leaving. For example, the owners might pick up their keys or purse, put on a coat, or open and shut the door without actually departing. This can be repeated two to four times a day but it is essential that the dog be calm between presentations. The process is successful if the dog no longer responds to the presentation of the identified cues with anxiety. Owners are also counseled to ignore the dog for 15 to 30 minutes prior to departure and upon return to keep these times neutral and calm.

Counter Conditioning to Departure

Teaching the dog to engage in an alternate activity when the owner approaches the door and/or departs may help some dogs cope more easily with owner departure. This can be a simple "sit/stay" or the use of a food stuffed toy prior to departure. The dog can also be asked to settle in its previously learned safe location.

Graduated Planned Departures

The goal is to replicate real departures, using a new signal to facilitate the dog learning that departures need not produce anxiety. Because these are difficult to properly execute, a more detailed explanation follows below. These are generally not begun until the dog can settle and relax on cue and no longer responds to departure cues with distress.

Actual Departures During Treatment

Most owners must still continue to work while treating the pet. Alternate solutions may be useful until treatment begins to change behaviors. These can include doggy daycare situations, pet sitters, and boarding. Confinement may be problematic for some pets and increase their anxiety and subsequent damage to themselves or owner property.

GRADUATED PLANNED DEPARTURES

Graduated planned departures are best started after the dog has been habituated to pre-departure cues. Using short departures, the goal is to desensitize the dog to the owner leaving and being gone. These departures are as much like real departures as possible with two exceptions. First, the departures are going to initially be **very** short. Second, as the owner departs they leave a new and consistent cue or signal for the dog. The goal is for the dog to associate the owner departure, the new signal and good behavior with each other as the dog learns how to left alone. Then the initial departure will be very short, 1 to 5 minutes or less so that the dog does not engage in any separation related behaviors. ***But, they will leave the dog a new cue or signal like the radio or television or air freshener to aid the dog in distinguishing this departure from a real or work departure.*** The goal is for the dog to learn "the owner is only gone for a short time, they are coming right back and I can be good." The length of the departure is **slowly increased** at 3- to 5-minute intervals with short departures interspersed with longer ones. The increase must be irregular, not a progression. The new cue is only used on a planned departure, *never* when the owner must be gone for long periods of time such as going to work. If the dog is destructive or engaged in any separation-related behaviors during a planned departure, then the owner was gone too long and the next departure should be shorter. For dogs that vocalize on owner departure, an audio tape should be set to monitor the pet's behavior. Owners must keep initial departures short enough so as not to elicit separation distress. When desensitization is done improperly, sensitization can occur and the problem behavior worsens.

Once a dog can be left on a planned departure for 2 hours, they can usually be left all day. The cue or signal can be gradually phased out, or can be used for as long as the owner feels it is necessary. Most importantly, the owner cannot quickly go from a 20-minute planned departure to a 3-hour one. This can elicit separation-related distress and may render the cue useless. During training, owners should be encouraged to keep journals to assess progress and treatment success. In many cases, once the dog can be left alone on a planned training departure for 2 hours, the dog can stay alone all day.

The use of barriers and crates must be evaluated in each case. For many dogs these actually heighten, rather than lessen anxiety. If the owner is willing to leave the dog out of the crate or not barricaded in a room during training departures this can be useful to help the dog distinguish these departures from routine work related departures.

Punishment must be avoided even if the pet has been destructive or eliminated while the owner was gone. Punishment increases anxiety and is not productive or helpful in resolving the problem behaviors.

DRUG AND PHEROMONE THERAPY

Many drugs have been used in the past for the treatment of separation anxiety in dogs. These include: tricyclic antidepressants, selective serotonin reuptake inhibitors (SSRIs), buspirone, and benzodiazepines. Prior to medications a physical examination and a minimum database of a biochemical screen, complete blood count (CBC), and urinalysis should be performed. Results with drug therapy may not be seen for 14 to 30 days, the owner must be committed to continue usage. Two drugs are presently formulated and licensed for the treatment of separation anxiety in dogs; clomipramine hydrochloride (Clomicalm®)[a] and fluoxetine (Reconcile®)[b] are now labeled to aid in treatment of separation anxiety. Tricyclic antidepressants (TCA) as a class of drugs primarily affect serotonin, norepinephrine, acetylcholine, and histamine. TCAs are contraindicated in hyperthyroidism; seizure disorders; in animals on thyroid medication, amitraz, or selegiline; or animals experiencing problems with urinary retention or urine flow. Common side effects with TCAs include urinary retention, constipation, tachycardia, dry mouth, hypotension, and mydriasis. Clomipramine is dosed at 2 to 4 mg/kg per day either as one dose or divided twice daily. The most common adverse reactions are vomiting, diarrhea and lethargy. Caution is advised in using clomipramine with other CNS active drugs including general anesthetics and neuroleptics, anticholinergic and sympathomimetic drugs. In the placebo-blinded drug approval study, the medication was used in conjunction with behavior therapy and withdrawn after 2 months. After week one, 47% of the dogs receiving clomipramine and behavior modification showed improvement compared with 29% of the dogs receiving behavior modification alone. In another placebo study by Podberscek et al on treatment for separation anxiety, it was found that the clomipramine patients either at a low dose (0.5–1.0 mg/kg bid) or a high dose (1.0–2.0 mg/kg twice daily) showed no greater improvement than those on placebo. However, behavioral therapy on its own was highly effective.

In a large multicentered double-blind, placebo-controlled study, fluoxetine was dosed at 1 to 2 mg/kg once daily. Dogs in both groups received behavior modification. Seventy-three percent of dogs treated with medication and behavior modification showed improvement in overall severity scores compared with 51% of behavior modification alone dogs at the study conclusion after 8 weeks. Forty-two percent of treated dogs showed improvement within the first week. In this study, the frequency of adverse events was generally similar for fluoxetine- and placebo-treated dogs. The most common adverse events reported following fluoxetine treatment were lethargy and vomiting. Seizures occurred in three fluoxetine-treated and one placebo-treated dog; therefore, fluoxetine is not recommended in dogs known to suffer from a seizure disorder. Full details of the study are recently published. Fluoxetine should not be used concurrently with monoamine oxidase inhibitors (selegiline and amitraz).

Fluoxetine and clomipramine should not be used concurrently due to the risk of producing serotonin syndrome. When either is used in a treatment program, the medication must be given daily and may take 2 to 4 weeks to see some effect. Patients may need several months of treatment for sustained improvement to be noted. In some cases withdrawal of medication may result in the return of symptoms.

Benzodiazepines have often been suggested for immediate relief or short term control. Benzodiazepines such as alprazolam (0.02 to 0.1 mg/kg orally) can be dispensed on an as-needed basis shortly before departures. Benzodiazepines may inhibit learning, usually require frequent dosing and may cause dependence and a rebound anxiety when discontinued.

DAP® (Dog Appeasing Pheromone)[c] may be useful in reducing anxiety associated with owner departure in some dogs. DAP is available as a diffuser that plugs into the wall and remains active for 30 days. One study comparing the efficacy of DAP versus clomipramine for the treatment of separation distress in dogs found to be them to be approximately equal with respect to owner global assessment scores and there were no significant differences between the two groups in individual signs.

PROGNOSIS

Takeuchi et al evaluated treatment outcome in dogs with separation anxiety and owner compliance and perception of effectiveness of treatment recommendations. Fifty-two dogs were evaluated and the researchers found that 32 were improved and 20 were the same, worse, or had been euthanized or given away. Significantly fewer dogs whose owners were given more than five instructions improved or were cured when compared with those given fewer instructions. This may reflect the difficulty of compliance, time commitment, or lack of understanding of the treatments prescribed. Twenty-seven were treated with medication (often amitryptyline probably because cases were from 1993-1997) and 15 improved. Owners complied with instructions that required little time such as chew toys at departure, increasing pet exercise, and omitting punishment. Often owners were not willing to uncouple departure cues or desensitize to impending departures.

WHY TREAMENT RESULTS VARY AND MAY FAIL

- Drug therapy alone is rarely curative for most behavioral disorders. Realistically, drug therapy can be expected to decrease the anxiety associated with owner departure. However, the drug alone will not change behavior and will not “teach” the pet new behaviors. While some behavior may be decreased, some will persist and even at high levels.
- If the pet is not taught how to remain home alone, and anxiety-producing cues are not habituated to, very little improvement might occur. In fact, some dogs may become worse.
- Concurrent additional anxieties (storm phobias, noise phobias, inter dog aggression issues) that are not addressed may limit treatment success
- Owner expectation of a “quick” cure. Owners are used to pharmacological treatments from their veterinarian resulting in a fairly rapid response from their pet. This usually does not occur with behavioral drugs.
- The ongoing destruction, vocalization, and elimination continue to strain the human–animal bond

IMPROVING PROGNOSIS

Because behavior disorders take time to diagnose and treat, veterinarians need to set aside a separate appointment to discuss the problems and completely explain the treatment plan. Emphasis on habituation, changing the pet–owner interactions and changing the leaving and return are important and relatively easy for owners to implement. Because it is easy to make the dog worse through improperly applied techniques, it is extremely important that the practice set aside time for regular follow up with owners of dogs with separation anxiety. Continued information and feed back is needed to see if the owners are properly administering the behavioral treatment plan. Owner journals can help assess progress and are often essential to monitor progress. Finally, medication can take 2 to 4 weeks to have an effect on behavior and must be given daily, not on an as needed basis. Therefore, it is crucial that the veterinary staff supports the owner's work with behavior modification. When no response is noted, the diagnosis should be re-evaluated and other concurrent behavioral problems also addressed.

An initial response to therapy is usually seen in 2 to 6 weeks depending on the number of trial departures that the owner is able to do and how the pet responds to the other components of the treatment plan. Total treatment time may be several months, for some dogs 6 months or more. Once the dog can reliably be home for 6 to 8 hours in all situations without the previous separation-related behaviors occurring, medication can be decreased. The dosage should be decreased at 25% per week while watching for reoccurrence of target behaviors. This is absolutely essential. If the dog begins to show any anxiety, either stay at that level for a longer period of time or increase back to the previous level. Early withdrawal of medication may result in the return of the separation anxiety and possibly are higher levels that before.

SEPARATION ANXIETY IN DOGS, PART 1: DIAGNOSIS AND CLINICAL PRESENTATION– AN EVIDENCE-BASED APPROACH

Gary Landsberg, BSc, DVM, MRCVS, Diplomate ACVB
Doncaster Animal Clinic
Thornhill, Ontario, Canada

The sensitive period in which puppies develop social attachments to the living environment (people and other pets) and to nonliving parts of the environment (localization or site attachment) is between 3 and 12 weeks of age. The process of becoming more fearful may begin at 6 to 8 weeks of age, but generally social attraction outweighs wariness until an upper limit of about 12 weeks. Socialization to a new species may be possible after this age but may take months of exclusive contact. Of course this upper limit may vary between breeds and individuals and without continued socialization further regression might occur.[1,2]

The mother or primary care giver provides a secure base from which the young begin to explore their world and gain confidence. Puppies become distressed if separated from their mother at three weeks, which rises to a peak at about 6 to 7 weeks and then declines at 12 to 14 weeks. However, puppies that are first separated from their mother at 9 to 12 weeks may exhibit more stress than puppies that have had previous separation. Separation vocalization and separation destruction are intended to restore contact with mother, social group, or care givers.[1-4]

Domestication and selective breeding may lead to increasingly affectionate, socially dependent and infantilized dogs which may inadvertently lead to excessive owner attachment and intolerance to being left alone.[1,5] Puppies that come to expect excessive social interactions following adoption at around 3 months may be unable to handle subsequent decrease in social interaction, and may become sensitized to departures.[6,7] Therefore, gradually introducing puppies to separation and enforcing time away from puppies may help them better cope with spending time alone.[1,6-8] In addition, puppies vaccinated prior to 8 to 9 weeks were at lower risk for separation anxiety.[1] On the other hand, providing extensive social experience between 5 and 10 months may be associated with an absence of separation anxiety.[6]

Mothers who are anxious or ambivalent may lead to more clingy, over-dependent infants who are distressed by separation.[1] In addition, dogs that were ill as puppies have also been shown to develop more separation related barking.[1] While these early experiences may influence the development of separation anxiety, it is most likely that genetics plays a primary role in the disorder.[1,4,5,6,8] Genetic variability may vary between individuals or there may be breed prevalences.[9] When separation distress reactions persist beyond the puppy stage they are maladaptive and may be indicative of a either dysfunctional attachment or perhaps even a pathological state.[5,10-12]

Since drug and pheromone therapy have been shown to be effective in reducing attachment behaviors and improving separation anxiety (in conjunction with behavior modification), compared with behavior modification alone, this may further indicate that neurochemical factors contribute to separation anxiety.[13-19] In fact, although concurrent behavior management is a necessary part of an effective treatment program, in one study fluoxetine alone had some beneficial effect on reducing anxiety even without the addition of behavior therapy.[19] In another study, clomipramine treated dogs had less solicitous behaviors and were overall more calm.[20] In another study dogs that were timid fearful and restless when removed from their social environment, the dogs were less socially solicitous and could be better trained to sit when treated with low dose morphine (0.25 mg/kg) and morphine treated animals were less socially solicitous.[21] When treated with naloxone the problem was aggravated and dogs were more solicitous.[21] In another recent publication, prolactin levels were found to be significantly higher in dogs under chronic stress, but significantly lower with fear and mild phobias, which indicates that anxiety disorders may differ in neurochemistry and in the drugs with which they might be treated.[22]

Separation anxiety may also arise as a secondary or acquired condition or have a learned component. For example, separation anxiety may arise when a dog is suddenly separated from its owners following a period of prolonged, constant or exclusive contact or a sudden change in routine.[1,7] These dogs may develop an overly intense attachment and may then be unable to with separation. In addition, separation anxiety may develop in individuals that have other anxiety disorders, such as noise and storm phobias and separation anxiety.[23-25] These dogs may become dependent on the owners to alleviate their anxiety and in turn, the owners' responses, whether reinforcement or punishment may further intensify the behavior. Yet, some of these dogs are well adapted to remaining alone at certain times or in certain environments, eg, cars.[3,5,12] This may be due to the absence of specific departure cues that lead to an anxiety or a difference in the owner's response to the dogs at certain times or in certain places. In the French literature, separation distress that occurs in the adult dog may be considered a depressive disorder, in which the destructiveness, vocalization and other autonomic signs of separation anxiety, which may even be displayed. Pre-sleep anxiety, sudden awakening, elimination during sleep, altered appetite and depression are also frequent signs.[11]

CASE DISTRIBUTION

Separation anxiety represents from as low as 9% to as high as 35% of cases referred to veterinary behaviorists.[3,7,23,31] However, in senior dogs, 29% to 50% of referred cases may be due to separation related distress.[28-30] This may be due to concurrent underlying medical problems, reduced cognitive capacity or the fact that older pets are less adaptable to change and stress especially a change in routine or death of another dog or family member. Therefore while a diagnostic evaluation including physical examination and laboratory screening is an essential step in any veterinary diagnosis, and prior to any drug use, it is of particular importance in the adult or senior pet that develops separation anxiety.

However, the prevalence at these referral practices does not necessarily represent the prevalence amongst dog owners in general. In one survey, 14% of dogs receiving regular veterinary care reported signs associated with separation anxiety,[5] while in a study of veterinary surgeons in the UK, it was estimated that about 15% of dogs have separation anxiety.[31] In a survey commissioned by Lilly (internal data) the prevalence was found to be as high as 17% of all dogs, yet only about 10% of these have been identified. This reporting rate is similar to a study in the UK in which 29% of 94 pet owners reported separation anxiety, but only 6 of the owners had sought assistance.[6]

FACTORS ASSOCIATED WITH SEPARATION ANXIETY

Source

A number of studies have indicated that shelter dogs are overrepresented in cases of separation anxiety.[14,22,23,32] However, other studies have found no correlation.[6,27] In fact in one study 33% of dogs were from shelters,[33] and in an Australian study in which 68% had been obtained from breeders or friends, the authors speculated that the lower proportion of shelter dogs may have been due to increased shelter dog screening.[34] Therefore, it appears that for the most part that when shelter dogs are overrepresented, it is because they already had separation anxiety at the time of relinquishment.[32,35-37] In fact, screening and assessment of shelter dogs, and provision of appropriate advice to those who adopt these pets can effectively reduce separation anxiety.[32,34-36] On other hand it is also interesting to note that dogs that experience the loss of an attachment figure may develop more insecure attachments,[1] and that dogs that dogs that had been previously abandoned were more anxious and had less secure bonds with their owners than puppies that had been with their owners since puppyhood.[37,38]

Sex, Breed, and Household Factors

If one were to examine individual studies then breed and sex trends are evident. However, by comparing numerous studies using a variety of methodologies and populations, there appears to be no breed or sex correlation. In some studies mixed breeds were more prevalent,[3,23,25] while in other studies there was no difference between pure and mixed breed,[6] or purebreds were more commonly represented.[33,34] Some studies have indicated that males are more commonly affected,[3,6,13,20,39] and one study indicated that intact males and females were one third less likely to display separation anxiety.[23] However, in one European study, there was no difference in sex distribution although there was a higher percentage of intact males and females (but neutering is far less common in some European communities), although there was no difference in sex distribution.[16] By contrast fears and anxiety are reported to be higher in females than males.[9] However, a large number of studies have found no correlation between sex and neuter status.[6,20,26,27,34] The presence of another pet has been consistently shown not to be protective.[23,27,34,40] Another study looked at age of adoption and found that puppies adopted prior to 12 weeks were at no greater risk.[23] Two studies specifically examined family makeup and conclusions were contradictory. In one study a single owner was 2.5 times more likely to have a separation anxiety problem than multiple owner homes.[23] However, in another couples with children were overrepresented.[34] Most other studies did not evaluate family makeup.[13,15,16,19,20]

The Relationship Between Training and Separation Anxiety

Although one study found no association between spoiling, obedience training and behavior problems.[31] A number of more recent studies have found a trend toward less separation anxiety and less behavior problems in dogs that have had obedience training.[14,40,42] In fact, dogs that have obedience training, have been trained with positive reinforcement, or have been to agility classes are less likely to have behavior problems, while those dogs trained with punishers had lower obedience scores and a higher level of training problems.[43,44]

DIAGNOSIS AND CLINICAL SIGNS

The most common signs of separation anxiety are vocalization, destructiveness, and, to a lesser extent, house soiling during the owner's absence.[3,5,7,11,23,23,40] Since the anxiety is due to the dog's anxiety is due to its inability to gain access to the owners, the behavior is not likely to be seen when the owners are at home and the dog has access to the owners. When owners are at home dogs with separation anxiety also commonly exhibit extreme following, continuously seeking contact, departure cue anxiety, rarely spending time outdoors alone, and excessive greeting.[3,7,23] When the owners depart, destructive activity is often focused on doors, confinement area exits, or owner possessions, such as clothes and furniture.[3,5,7,23] Many of the signs are directly related to the autonomic arousal that accompanies anxiety. Concurrent signs of depression, anorexia during departure (which resumes when the owner is home), vomiting and diarrhea, and hypersalivation are highly supportive.[5,7,23,39] Other concurrent signs may include increased motor activity,[3,5,40] excess licking or grooming,[15,16] restlessness,[15] shivering and shaking,[16] stereotypic or repetitive behaviors such as acral lick dermatitis, ritualized circling and pacing,[5,13,40,45] and occasional reports of aggression as the owners prepare to depart.[3,7,46] Most signs tend to arise within the first 30 minutes of departure and many appear prior to, during or immediately following the owner's departure.[3,7,39,40] Signs may decrease over time or have a cyclical nature to their recurrence ranging from 25 to 28 minutes[40] to 40 to 60 minutes.[39] In addition, external stimuli also lead to rearousal.[40] The distribution of signs as collected from the various published studies are listed in Table 1.

Prognosis

In a study of 52 dogs that were followed up 6 to 64 months after their visit, 32 dogs (62%) improved; 24 (46%) improved and 8 (16%) resolved. Twenty of the dogs were the same, worse, or had been euthanized or given away (7 same, 3 worse, 5 euthanized and 4 given away).[39] In this study, 27 dogs were treated with amitriptyline and 56% improved. However, recent studies combining clomipramine, fluoxetine or DAP with behavior modification achieved much higher results (see Part 2 of this article).

Significantly fewer dogs were improved or cured when owners were given more than five instructions. Owners complied with instructions that required little time, such as chew toys at departure, but were less willing to institute more difficult tasks such as uncoupling departure cues or desensitizing the pet to departures.

While a comprehensive behavior consult with case-specific instructions that are tailored to the owner's needs might be most successful in an owner who is willing and compliant,[20,47] studies have shown that success can generally be achieved by combining a simplified behavior modification program with a drug or pheromone that reduces underlying anxiety.[13-18,48]

Table 1. Distribution of Reported Signs

- **Destructive:** 90%[40], 84%[7], 83%[19], 80%[3,15], 76%[13], 72%[16], 71%[23], 62%[17]
- **Vocal:** 96%[40], 90%[3], 73%[13], 67%[16], 61%[23], 48%[17], 41%[7]
- **Eliminate:** 55%[3], 53%[16,17], 28%[23], 18%[7], 5%[40]
- **Urinate:** 42%[19], 36%[13], 34%[15]
- **Defecate:** 37%[13], 32%[19], 27%[15]
- **Salivate:** 43%[19], 35%[15], 17.5%[16]
- **Feeding:** 46%[16]
- **Licking:** 40%[16]
- **Sleep:** 23%[16]
- **Vomiting and diarrhea:** 19%[23]
- **Stereotypic or displacement;** 10%[40]

SEPARATION ANXIETY IN DOGS, PART 2: THERAPEUTIC OPTIONS – AN EVIDENCE-BASED APPROACH

Gary Landsberg, BSc, DVM, MRCVS, Diplomate ACVB
Doncaster Animal Clinic
Thornhill, Ontario. Canada

A behavior management plan is required to help the pet reduce its overdependence on the owner and to train and shape behavior to achieve a calm and relaxed state even when the owner is not present. However, as discussed in Part 1 of this two-part article, because the attachment is generally dysfunctional, the anxiety can be quite intense and there may be other concurrent fears and anxieties co-existing. Therefore, when behavior modification is combined with drug or pheromone therapy a faster and greater improvement has been shown to be achieved.[13,15-18,39.48] Drug therapy may also initially be in the best interest of the anxious and panicked pet until it can learn to better cope with owner departures, and may improve the pet's ability to learn. In one 6-week study, the use of a drug alone (fluoxetine) led to improvement in overall severity in comparison to placebo at all time points; however, statistical improvement was not achieved in as many parameters nor at as many time points as in other studies where behavior modification and drug were combined.[19] In addition, it should be noted that fluoxetine is licensed only for use with concurrent behavior therapy. On the other hand, in another study behavior modification alone appeared to be no less effective than the combination of clomipramine and behavior modification.[20] In this study, clomipramine appeared to have a sustained effect at reducing general activity as well as a modest suppression of attachment-related tendency to seek physical contact. However, the groups in this study were small; there were differences at baseline, and an extensive behavior modification program was utilized which included denying access to the bedroom, stopping all interaction one hour prior to departure, and physically separating the dog from the owners with a dividing door or gate when the owner was at home. However, at least from an American perspective, the prognosis appears to be poorest when more instructions were given (>5) and owners are less willing to comply with tasks they find more difficult.[39]

EVIDENCE-BASED MEDICINE

Evidence-based decision making is a means of providing the best information and treatment options that evidence has to offer. The validity of the information, the fundamentals of all clinical trials and their trial design, and the application of statistics is necessary to properly appraise the evidence. The final therapeutic approach should then be selected using the evidence combined with the clinician's expertise as to the patient, client, and problem. Assessing outcomes further enhances the process. In veterinary medicine; however, there is limited availability to the process.[49] Many sources of veterinary information fall in the poorest (D) level including personal experience, colleague opinion, non-veterinary expertise, continuing education notes, textbooks, internet, or inconclusive studies of any kind. Studies based on in vitro research or from another species also likely fall into this category. At the other extreme, the most desirable level (A) are systematic reviews with homogeneity or randomized controlled clinical trials (RT). Where the assessment of multiple randomized controlled clinical trials is not possible, then a single randomized control trial with high confidence would be the next best option. At the next level (B) are systematic reviews of cohort studies with homogeneity (comparing groups that received the treatment to those that did not), an individual cohort study or lower quality RTs, or outcomes research and population studies. Case series or poor quality cohort or case control studies would get a C rating.

DRUG THERAPY FOR SEPARATION ANXIETY – SHOW ME THE EVIDENCE

As mentioned, drugs can be used in conjunction with behavior modification to reduce the pet's anxiety, improve learning, and help it to better cope with owner departures especially during the first few months of training. In placebo-controlled studies using fluoxetine plus behavior modification, a significant improvement was achieved over behavior modification plus placebo.[13,15,17,18,48] While these antidepressants may achieve peak plasma levels within hours, this does not reflect their therapeutic effect since reuptake inhibition may induce downregulation of post-synaptic receptors that are responsible for the clinical effects. Therefore, while improvement may be seen within the first week or two of the program, treatment should be maintained for at least 2 months to determine the full effect of the drug plus behavior program.

Fluoxetine

Fluoxetine is a selective serotonin reuptake inhibitor (SSRI) that has recently been licensed in the United States for the treatment of separation anxiety in dogs at a dose of 1 to 2 mg/kg per day in conjunction with a program of behavior modification. Prior to the North American trial, pharmacokinetic studies were performed indicating a T_{max} of 1.8 hours for fluoxetine and 12 hours for its active intermediate metabolite norfluoxetine, and a clearance half life of 6.2 hours for fluoxetine and 49 hours for norluoxetine. A multi-site placebo-controlled dose determination study of 394 dogs at 47 veterinary practices in Europe (which is as yet unpublished) comparing various doses of fluoxetine plus behavior modification to placebo plus behavior modification, determined that the optimum dose that achieved significant improvement over the placebo group without any significant side effects was 1 to 2 mg/kg per day.

In a multi-center 9-week North American trial of 197 dogs using a dose of 1 to 2 mg/kg (0.45 to 0.91 mg/lb/day), after 8 weeks of treatment with fluoxetine chewable tablets (FCT) plus a behavior modification plan (BMP), there was a significant improvement in overall severity scores over the placebo plus BMP group: 73% of FCT plus BMP dogs were improved compared with 51% in the placebo plus BMP group. In fact, after the first week of treatment 42% of dogs treated with FCT plus BMP had improvement in overall severity scores compared with 18% of the placebo plus BMP group. Destructiveness, vocalization and restlessness were all significantly improved at each week of the trial except for week 3 for destructiveness and weeks 1, 3, and 4 for vocalization. In the safety evaluable group there were 229 dogs. Calmness, lethargy, and anorexia were the most commonly reported side effects. No significant changes in any of the blood parameters were seen through the course of the study. The beef-flavored chewable tablets were also determined to be palatable to treated dogs and easy to administer.[15]

In a second multi-center 6-week trial of 208 dogs in the US and Canada, the efficacy of fluoxetine chewable tablets (FCT) was compared with placebo in the treatment of separation anxiety. Overall severity scores were improved over the placebo group at all weeks with significant improvement at weeks 1 and 4. Destructiveness was also improved at each week with significant improvement at weeks 4 to 6, while urination and salivation were also improved at each time point but statistical significance was not achieved. This trial therefore indicated that there was a measurable drug effect but that greater and more significant improvement could be achieved using a combination of behavior modification and fluoxetine. In fact, the drug is recommended and licensed for use only in combination with a behavior modification program. [19]

Although there are no other licensed uses for fluoxetine in dogs, there is also evidence that fluoxetine may be useful in the treatment of generalized anxiety disorders.[50] Fluoxetine has also been demonstrated to be effective in the treatment of compulsive disorders in dogs.[51-54]

If anorexia or weight loss is significant, the dose may need to be reduced. SSRIs should not be used concurrently with other antidepressants or monoamine oxidase (MAO) inhibitors (eg, selegiline and amitraz). Since SSRIs inhibit cytochrome P-450 enzymes, they can lead to increased toxicity when combined with drugs that are metabolized by these enzymes.

Clomipramine

Clomipramine is a tricyclic antidepressant (TCA) that inhibits serotonin reuptake and, to a lesser extent, noradrenaline reuptake. It also has anticholinergic and antihistaminic effects, which might account for some its side effects, such as lethargy, dry mouth or gastrointestinal upset which are generally mild and transient.[13,17] Tricyclic antidepressants are contraindicated with cardiac disease, glaucoma, where urine retention is a concern. However, clomipramine appears to be associated with less urinary stasis, cardiac disease, and anticholinergic effects in dogs in comparison to its use in humans because of its shorter half-life and its rapid elimination. In addition the ratio of clomipramine to desmethylclomipramine is higher in dogs (3:1) than humans (1:2.5) and desmethylclomipramine is likely responsible for most of the noradrenergic and anticholinergic side effects.[54] Clomipramine has a time to peak concentration of about 1.6 hours for clomipramine and 1.2 hours for its active intermediate metabolite desmethylclompramine, and has a half life of about 4 hours and reaches a steady state in about 4 days.[55] As with other drugs in this class, 4 to 8 weeks of therapy is generally recommended to fully assess therapeutic effects.

Clomipramine is licensed for treatment of separation anxiety in dogs in a number of countries in conjunction with a program of behavior modification at a dose of 1 to 2 mg/kg twice daily. However, in the US the label claim recommends a dose of 2 to 4 mg/kg either as a single daily dose or divided twice daily, although most published studies have utilized twice daily dosing.[13,14,16-18,48] Studies have demonstrated that clomipramine in conjunction with behavior modification provides significant improvement over placebo plus behavior modification. In one study after the first week, 47% of dogs receiving clomipamine plus behavior modification showed improvement compared with 29% of the dogs receiving behavior modification alone.[13] After 4 weeks the improvement with clomipramine plus behavior modification had reached 63% compared with placebo alone and this trend continued through 8 weeks of treatment although significance was not achieved.[13] More dogs were improved in the clomipramine group for destructiveness, urination and defecation but statistical significance was not always achieved.

In a follow-up study of 76 cases, 12 dogs had been on ongoing treatment for over 13 months with no adverse effects or relapse, and 10 of the dogs showed further improvement. Of 22 dogs with complete resolution when the drug was ceased, 13.6% relapsed. Therefore, it is likely that some dogs will require or benefit from a much longer course of drug therapy.[14]

In some countries clomipramine is also licensed for the treatment of other anxiety disorders and compulsive disorders. Clomipramine, in combination with BMP, has also been used for the treatment of storm phobias in combination with benzodiazepines on the day of storms.[56] Clomipramine is also effective in the treatment of compulsive disorders in dogs.[53,57-59]

Tricyclic antidepressants should not be used concurrently with MAO inhibitors such as selegiline or amitraz and should be used cautiously in pets with seizures.

SSRI or TCA

When comparing a TCA such as clomipramine to an SSRI such as fluoxetine, the potential for side effects is theoretically greater with the TCA since there is the potential for anticholinergic, antihistaminic, and alpha-adrenergic blockade as well as both serotonin and noradrenaline reuptake blockade, compared with the serotonin selective reuptake inhibition of fluoxetine. In one study amitriptyline led to tachycardia and hypotension compared to fluoxetine.[60] However, in several trials, clomipramine has been shown to have no cardiac effects on healthy dogs and no significant effects on intraocular pressure.[61,62]

DAP

DAP is a synthetic version of the intermammary appeasing pheromone that has been identified in the lactating bitch. A diffuser formula of DAP was compared to clomipramine in 67 dogs showing signs pf separation anxiety. All dogs received behavior modification and the owners were given either clomipramine and placebo DAP or DAP and placebo clomipramine. Behaviors improved in both groups over a 28-day trial with no significant difference in overall improvement between the two groups.[0]

Other Therapeutic Options

Where a more immediate response is required SSRIs might be combined with benzodiazpines or used concurrently with aromatherapy or other natural products such as l-theanine or melatonin that might help to reduce anxiety.[63-66] However, no controlled trials have been done to assess the efficacy of benzodiazepines or other therapeutic agents in the treatment of separation anxiety. Fluoxetine and clomipramine might also be used concurrently with DAP.

Selegiline might be indicated in the older dog with signs of separation anxiety that might also be associated with cognitive dysfunction. However, selegiline cannot be used concurrently with SSRIs and TCAs. Recent European studies have also shown that selegiline might be useful in dogs with chronic states of stress and high anxiety states, especially those associated with autonomic arousal and stereotypic behavior. In these dogs, prolactin levels were found to be elevated.[22] Selegiline was also effective in four dogs with social and sound phobias at a dose of .5 mg/kg per day along with a combination of propranolol and alprazolam for days with thunderstorms or fireworks.[67] In a preliminary study, selegiline and alpha-casozepine both led to significant improvement in anxiety disorders of dogs.[66]

BEHAVIOR MODIFICATION CASE MANAGEMENT IN GENERAL PRACTICE

Patrick Melese, MA, DVM, Diplomate ACVB
Veterinary Behavior Consultants
San Diego, CA

Most of companion animal veterinary medicine exists to provide services to owners who largely enjoy their pet's behaviors. It is important for us to help clients that are having problems with their pets' desired behaviors. When that bond gets strained or broken, the pet is at risk of losing its home or life and the veterinary profession is at risk of losing a patient. Depending on the level of commitment and knowledge of the individual general veterinary practice, every office can provide some level of veterinary behavior services.

BEHAVIOR SERVICES FOR ANY PRACTICE

Any practice can provide owners with general advice on selecting and raising physically **and behaviorally** healthy pets, which also make better patients and clients for the practice.

First Vet Visit

- Sets tone for relationships with pet and owner
- Have enough time: book two time slots
- Use checklist to systematically cover items
- Decide what each team member will cover
- Assure good/great experience for puppy/kitten
    - Use highest value goodies and fun toys
- Send home puppy/kitten kit & include:
    - Behavior educational material
    - Appropriate toys, socialization treats, etc.

The 8- to 14-Week-Old Puppy Must Learn:

- Bite inhibition
- Housetraining
- Appropriate chew items
- Listen to owners
- Be left all alone
- Tolerate veterinary handling
- What/who will be part of its life (other dogs, cats, kids, different people, etc.)

New Kitten Must Learn:

- Not to bite or claw people
- Appropriate litter box use
- Appropriate places to scratch
- Tolerate veterinary handling
- What/who will be part of its life (other dogs, cats, kids, different people, etc.)

Provide or send clients to programs to teach owners how to properly **socialize** and raise new kitten or puppy. Puppy socialization classes (start at 10 to 12 weeks of age and avoid unwarranted fear of canine sensitive period overlapping with primary veterinary vaccination period as this is not realistically a significant problem with good infectious disease protocols in place) or at least "puppy parties." Do your "due diligence" and if your practice provides it be sure the instructors are well trained; if you send clients to an outside provider, be sure that provider is well educated, experienced and humane (they will reflect on your practice).

- Once adopted, puppy kindergarten/socialization classes can help start puppies and owner off "on the right paw."
- Start at at 10 to 12 weeks of age to take advantage of socialization period in puppies that ends at 16 weeks (4 months).
- Routine handling and mock "exams" along with treats and praise
- Helps to make a more tractable future patient and owner more bonded to their pet
- Basic lure/praise based obedience training can be of great help for dogs
- Start early before too many problems develop
- Appropriate collars, halters, and harnesses such as Gentle Leader® or Easy Walk® can be important training aids.
- Training should be humane, effective and fun.
- Progressive techniques should not rely primarily on the strength of the trainer or methods that cause pain and undue distress.
- Practice must inquire about and "triage" behavior presentations from pets of all ages to appropriate provider (unruly/disobedient vs. behavior problem).
- Identify medical presentations with untreated **underlying behavior causes** for example:
    - Traumatic wounds inflicted by another animal (eg, inter-dog/inter-cat social aggression, aggression to unfamiliar dogs)
    - Self-trauma (eg, panic attacks, compulsive disorders)
    - Foreign body ingestion/enterotomy (compulsive behavior, pica, inappropriate chewing, etc.)
    - "Backyard" dog or "outside" cat (increased risk) (unmanaged indoor behaviors such as chewing, house-soiling, destructive behavior, unruly, etc.)
- Work up potential behavior problems to rule out physiological ("organic") disease and/or get baseline lab database.

MAKING A GOOD REFERRAL

When should you refer your client to a Veterinary Behaviorist rather than a trainer? A progressive skilled trainer may be fine for:

- Untrained dog:
    - Needs "well care" such as COME, SIT, DOWN, DROP-IT, basic initial housetraining (not resistant adult IE problem) etc.
- Dog is mostly just unruly for example:
    - Jumping up on people
    - Runs away when called & does not listen to owners
    - Mouthing owners in play/excitement (barking at owner for attention, not only when alone),

analogous to child just needing to go to a decent credentialed teacher at good public school.

If a behavior problem presents, a professional trained for problem animal behavior will likely be needed, preferably a boarded veterinary behavior specialist (Diplomate ACVB).

- Trained and credentialed to work up and assess any kind of animal behavior problem (not just dogs) and have **all treatment modalities** available to use as most appropriate.
- Analogous to a child having been in good public school (or missed out) BUT now needs an Individual Education Program (**IEP**) developed (= treatment plan) incorporating appropriate components.

Know Your Behavior Professionals
Credentials/representations:

- **Meaningful** (Academic training and experience required, certification process)
  - Diplomate ACVB (Veterinary Behaviorist)
  - Certified Applied Animal Behaviorist (CAAB)
- Generally **not meaningful** (self promotion with no universally accepted criteria)
  - Behaviorist, dog psychologist, animal behavior specialist, "dog whisperer," offers: "behavior modification," "private" certification
- Generally legal to make these claims as long as not a veterinarian

Best referrals to a board-certified Veterinary Behaviorist have:

- Motivated owners with appropriate expectations and understand the need to commit some time & financial investment in their pet to solve behavior problems (most are chronic conditions and unlikely to be an "easy fix").
- "Organic" problems have been ruled out (though, again, not typically required if problem appropriate).

Finding a Behaviorist in your area:

- American College of Veterinary Behaviorists (ACVB) www.dacvb.org
- Animal Behavior Society Certified Applied Animal Behaviorist (most NOT veterinarians but do have credentialing program) www.animalbehavior.org
- Call nearest VMA or Vet School for specialist in your area.
- If no boarded specialist around, you may find a veterinarian with a special interest in behavior problems (eg, AVSAB dues paying member but **no** credentialing program www.avsabonline.org)

Logistics:

- Client will typically call the specialist's office and make an appointment. Like other specialists, Veterinary Behaviorists usually cannot drop their case load and speak with potential owners before appointment.
- History, behavior exam, diagnosis, treatment and prognosis are all part of the behavior appointment.
- Initial appointments are typically 1.5 to 3.5 hours long depending on problem, history and provider.

WHAT HAPPENS DURING A TYPICAL BEHAVIOR APPOINTMENT?

- Detailed History and exam/evaluation
- Diagnosis and discussion with client
- Treatment Plan developed and explained/ demonstrated to owner
- Prognosis at initial visit
- Referral/case summary letter sent to referring practitioner.
- Rechecks and phone follow-up by owner as appropriate.
- If possible fill out specialist's **referral form** to facilitate the referral and summarize your medical & other knowledge of pet's relevant history.
- Give client practice **telephone number** and website (if appropriate) to call specialty practice for an appointment.
- Avoid discussing specific fee amounts ("***appropriate professional fees*** for doctor's time charged in line with other veterinary specialties"). Leave **details to specialty practice** since some clients will only hear the $$ figure without any context of what the value is and what they will get for their money. With the extensive time the specialist spends with your client and their case write-up and management, veterinary behavioral medicine is one of the best values for the money in the profession.
- Send appropriate medical records and lab data **after the appointment** has been made (FAX, mail or via client).
- Call if you feel that briefing specialist would be of extra value or just if you prefer to discuss the case before referring.

PRACTICES WITH MORE RIGOROUS COMMITMENT TO BEHAVIOR SERVICES

- Diagnose and suggest straight forward treatment plans for selected behavior problems-
  - Requires a general practitioner with an interest and **fundamental training in behavioral disorders**.
  - Appropriately trained staff can help teach clients with problems where medication is not used.

- Veterinarian with interest in behavior can diagnose and suggest simple treatments for selected behavior problems, especially when FDA approved medications are available or, at least, well established treatment protocols are published.
  - Uncomplicated dog separation anxiety case (Reconcile® and Clomicalm®).
  - Uncomplicated canine cognitive dysfunction in older dog (Anipryl®).
  - Uncomplicated inappropriate elimination cases in cats and dogs (no FDA approved treatments).

  - Other straightforward anxiety-related, excitable, and destructive behaviors in dogs and cats (no FDA-approved treatments)

RESOURCES

Practitioners and staff who wish to learn more about veterinary behavioral medicine can access various easily available sources including:

Web sites:

- American College of Veterinary Behaviorists: www.dacvb.org
- Dr. RK Anderson's (DACVB and co-inventor of Gentle Leader®) New Animal Behavior Resources Institute www.ABRIonline.org
- Animal Behavior Society's web site with section on Applied Animal Behavior credentialing (primarily if not already a veterinarian): www.animalbehavior.org
- Many others on web but always check sources.

Publications:

- "Starting a Behavior Program": a collection of articles from Veterinary Economics and Veterinary Medicine (800-255-6864)
- *Handbook of Behavior Problems of the Dog and Cat* (Landsberg DACVB, Hunthausen DVM and Ackerman DACVD) 2003 published by Saunders.
- *Puppy Class manual* from Premier Pet Products
- Lifelearn C/D (2002) containing 62 behavior handouts (Landsberg and Horwitz both DACVB) (800-375-7994).
- Pet Behavior Pamphlets by AAHA (800-883-6301).

Join Veterinary Behavior Interest Group:

- American Veterinary Society of Animal Behavior (AVSAB at www.avsabonline.org)
- Go to CE- Many national and regional conferences have behavior available including:
  - AVMA annual meetings (associated ACVB/AVSAB meetings)
  - Western Veterinary Conference (WVC)
  - The North American Veterinary Conference (NAVC)
  - The Central Veterinary Conference (CVC).
  - Local & regional Presentations by Veterinary Behaviorists
  - Annual "Association of Pet Dog Trainers" (APDT) meetings (www.apdt.com)

CHARGE FOR YOUR BEHAVIOR SERVICES

- Some of general behavioral advice noted above (eg, for all practices) may be included as part of your regular client services and not charged for additionally, but help you stand out from other practices and generate revenue from products and classes.
- More involved behavior workups, diagnosis, and treatment plans cannot be done during a routine medical exam (just like human patient with psychological problems can not be treated properly as part of routine yearly exam) and a distinct, longer behavioral appointment must be made. Charge will depend on doctor time and can be increments of routine appointment fee. It is often best to schedule these appointments just before lunch or at the end of day (schedule like euthanasia time slot) in case it runs over a bit from the anticipated time slot. Use an interested technician (send to CE, assign reading, join Veterinary Behavior Technicians Association, etc.) to help with client education/explain treatment plan just as we do with post op physical therapy, home dental care education, etc. The perceived value and compliance increases as you charge for your expertise and time. Use handouts (see above) along with well documented products (eg, Gentle Leader "system" packaging) to leverage your appointment time.

PROVIDING VETERINARY BEHAVIOR SERVICES

- Positive:
  - Additional **profit** center with some **profitable products**.
  - Helps further bond your clients to your practice.
  - Helps make for patients that are easier to handle.
- Negative:
  - Time consuming and hard to charge for that time.
- Even if you have a special interest in behavior, consider referring certain problems that are resistant to therapy; complex presentations/history; **aggression**, especially towards people
  - Caution with aggression between resident dogs-human at great risk when breaking up fights!
  - Use a Veterinary Behavior **Specialist** if possible.
  - Possible liability issue if you refer to lay person (always best to refer "up" in the profession).

SUMMARY

- **Any practice** can benefit and NEEDS to participate
- The level of integrating behavioral services only limited by **interest and training** of doctors and staff in the practice.
- Like with other veterinary specialties, **refer cases** that your practice is not trained to diagnose and treat; develop a good **referral system** to the nearest well-trained and effective behavior specialist.
- Help preserve and foster the human–animal bond that feeds the rest of your practice. Your clients will love it!

SPEAKING DOG – UNDERSTANDING HOW DOGS SIGNAL

Karen L. Overall, MA, VMD, PhD, Diplomate ACVB,
ABS Certified Applied Animal Behaviorist
Center for Neurobiology and Behavior,
School of Medicine, University of Pennsylvania,
Philadelphia, PA

The uniting feature that connects all social vertebrates is the extent to which they signal non-verbally. Communication involving ritualized displays or graded signals is used to confirm or reject information received from others in social interactions, to indicate species, sex, and sexual receptivity, to signal about issues pertaining to status, and to otherwise negotiate all social interactions. As such, communication can involve such instantaneous behaviors as tactile and visual displays. These are relatively "short-distance" signals. Vocal communication is also instantaneous, but may reach over longer distances. Verbal communication is only one variety of vocal communication, and both of these may pale when the full story of olfactory communication is written. Certainly, olfactory and pheromonal signals provide information that can be assessed over distances and across time.

When assessing any communicatory structure it is important to realize that signaling involves a set of rules that will be shaped by the evolutionary history of the species. The story of canine domestication is the story of work and work-related tasks. The story of feline domestication is the story of rodent and vector borne diseases and their prevention. These two divergent paths to domestic lifestyles have been shaped by, and in turn have continued to shape factors like reproductive schedules, fecundity, age at first reproduction, age at sexual and social maturity, composition of family or group units, and social interactions within these units. To understand such behaviors it is critical to understand the component signals as they are used to communicate with conspecifics. Table 1 provides an introduction to canine signaling.

WHY UNDERSTAND SIGNALING?

Understanding signaling is essential to taking a good history in behavioral medicine. The client tells you that "Fluffy is aggressive." This is a simple declarative statement, except we have no idea what it means. For one client, it can mean that the year-old dog was—and had been since puppyhood—tethered to a tie-down 23 out of 24 hours and tried everything, including grabbing the owner and leading her to the ball, to solicit play during her one hour of freedom. The action with the teeth seemed "aggressive" to the client and her desire to play with the dog decreased as the size of the dog and the desperation with which the dog sought play grew.

There is only one way out of this problem: collect data on the actual behaviors. Watch the dog when you are talking to the client, ask the client to interact with the dog the way they normally do, videotape the dog while you are doing this so that you can review the tape leisurely and learn something, ask the client to videotape the dog at home doing its normal routine, ask about specific behaviors. If you are unsure of something, put the dog in a different situation. If the client tells you that the dog barks when he sees other dogs on the street, ask if it's a "happy," multi-toned, high-pitched, greeting bark, or a sharp, repetitive bark often associated with distress, or a low, decrescendo, menacing bark. If the client says, "I don't know," thank them for their honesty and take the dog for a walk. Don't make it the client's responsibility to be omniscient. Let them know early on that not only is it okay to not know something, but that it's important for you to know when they are unsure so that you can collect the data. You don't have to go to the client's house to do this, and given that you automatically change the social environment when you do so, you might want to save home visits for situations needing further clarification. You can often do just as well and sometimes better with videotape of ordinary activities.

It's the difference between a judgment or interpretation and an **event** that is so critical in behavior and behavioral medicine. This means that you must see the dog and his or her behaviors. It's good science to do so since in behavior and behavioral medicine the data are the behaviors, and there is no excuse for not collecting the data to the extent possible. Part of doing science is to evaluate the quality of your data and ask if they are suitable for answering the question you asked. So when someone tells you that the dog is "shy," "fearful," "aggressive," "confident," "dominant," "submissive," "bored," "angry," et cetera, you should always, always ask yourself if what you were told contained information worth having. You should always confirm your assessment by asking: "Exactly what did he do? Was his tail up or down? Where were his ears? Was he making any sounds? What behaviors does he exhibit that makes you think he is "bored" (or "angry" or "shy"...)? If he is in XYZ circumstance, what exactly does he do and how often does he do it?" If the dog's person cannot answer these questions, well, you're at an excellent place to start: you know exactly which data they need to go home and collect.

EARLY INTERVENTION: ROUTINE SCREEN FOR BEHAVIORAL PROBLEMS

Most veterinarians obtain a routine history about physical complaints and concerns when they examine any dog or cat regardless of whether that pet is newly adopted or has been a beloved family member for a decade. We are all getting better about screening for geriatric health problems as we learn more about keeping pets happy and healthy for longer times. But the single biggest "health" problem faced by pet dogs and cats is still associated with behavioral pathologies or unmet behavioral expectations. Modern veterinary care should include routine screening about specific behavioral complaints in addition to routine questions that alert veterinarians to potential somatic medical problems. If we can ask "Any vomiting, diarrhea, changes in appetite?" we can also ask "Any inappropriate or undesirable chewing, any growling, any odd behaviors?" If we do this, we accomplish the following goals:

1. We initiate a dialog with the clients about behavior. This lets them know that not only is behavior important, but it is central to good veterinary care. Clients will then feel comfortable asking their veterinarian about behavioral issues. Such dialog represents our best chance for learning of a client's behavioral concerns before these concerns threaten the pet's life.
2. We establish a baseline of the particular pet's behaviors. Such a behavioral profile will allow us learn "normal" for that pet so that we have a context in which to evaluate behavioral change or client complaints about behavior. This is exactly what we are doing when we recommend routine laboratory evaluation for healthy pets...if we never knew when the pet last had a creatinine within the reference range it is difficult to know how long the creatinine has been elevated. Length of dysfunction—whether the dysfunction involves a "medical" or a "behavioral" complaint—can affect prognosis, and the extent to which this is true in behavioral medicine is profound.

A basic questionnaire for dogs that can be completed at each visit should be used (See: Overall, K.L. Manual of Clinical Behavioral Medicine for Small Animals, Elsevier, St. Louis, 2008, for one example). This questionnaire should be used at any and all visits to check if the clients have any questions or complaints. You have to remember that the clients might not even know that they have questions or complaints because they do not know what "normal" is. Also, if anything, myths about breeds, behavior, nature, and nurture are far more insidious in the client community than in the veterinary community. Finally, it's important to remember that the clients may not know what normal behavior is, or that they may be uncomfortable with a behavior, but not know how to ask if it is abnormal. This and more detailed questionnaires will give clients the vocabulary and opportunity to discuss their pet's behaviors with their veterinarian in an efficient and progressive manner.

References are available from the author upon request.

Table 1. Canine Signals

Signal	Circumstance Information
Barking	Alerting/warning Attention-seeking
Growling	Warning Distance-increasing
Crying, whimpering, whining	Et-epimeletic
Howling	Elicit social contact Anxiety situations (social contact = reassure)
Moans	Pleasure, contentment
Tail and ears up; forefoot in front of other	Alert, ready to participate
Direct gaze	Challenge Confidence Absence of threat Distance-increasing
Averted gaze	Fear 'Cowardice' (caution) Deference Absence of challenge (not the same as deference for confident, high-ranking dogs) Distance-decreasing signal
Belly presented	Deference - if neck back and other solicitation cues given Disengagement - if inguinal area and, or chest covered may become aggressive if pursued Relaxation - if flaccid
Tail tucked when belly presented	Fear/submission
Tail tucked when belly presented with urination	Profound fear/'submission'
Grin	Deference Distance-decreasing signal

Signal	Circumstance Information
Piloerection	Arousal associated with anxiety, fear, aggression Distance-increasing
Piloerection restricted to neck or tail region	Confident dog
Rigid stance, stiff torso musculature	Confidence and intent to interact (may not be aggressive) Distance-increasing
Tail above horizon	Confident High 'status'
Tail below horizon	Less confident Lower 'status' Deference Fear
Tail wag	Willingness to interact
Tail tip wag; stiff	Confident Assertive Offensively interactive
Neck erect or arched	Confident Challenging
Ears erect	Alert Confident
Ears back	Fear
Ears vertically dropped	Deference 'Submission' Low 'rank' Anxiety
Snarl/growl with only incisors and canines apparent	Confident Offensively aggressive Distance-increasing
Snarl/growl with all teeth and back of throat apparent	Defensively aggressive Fearful Distance-increasing
Body lowered	Defensive Distance-decreasing Fearful Deferential Relaxed
Licking lips, flicking tongue	Appeasement Et-epimeletic Distance-decreasing Anxious (and solicitation of reassurance; derived from et-epimeletic)
Raising forepaw	Distance-decreasing Solicitation of attention Deference (off balance)
Paws out, front end down, rump up, tail wagging	Body bow, invitation to play
Perpendicular posture	Challenge Confidence
Mounting or pressing on back or shoulders of another dog	Challenge Marking, claiming Asking a question about interaction; information seeking
Licking at corner of another dog's (or person's) mouth	Et-epimeletic Deference Solicitation
Blowing out lips/cheeks	Anticipation (positive or negative) Anxiety (if very fast)
Popping or snapping of upper and lower jaws (bill pops)	Capitulation, intention to comply as a last resort

UNDERSTANDING CATS WHO FIGHT AND WHY THIS AFFECTS LITTERBOX USE

Karen L. Overall, MA, VMD, PhD, Diplomate ACVB,
ABS Certified Applied Animal Behaviorist
Center for Neurobiology and Behavior
School of Medicine, University of Pennsylvania
Philadelphia, PA

FELINE AGGRESSION AND ASSOCIATIONS WITH ELIMINATION DISORDERS

Feline social systems differ from those of dogs in many ways, and their history with humans is worth discussing. Cats were likely never truly “domesticated.” Ancestral cats are not very different from modern cats in either size or habit. Cats have historically been found near and around human settlements, because where there are people there is stored food, and where there is stored food there are rodents. A mouse or a rat makes a single meal for the cat on the go. Accordingly, modern cats are solitary hunters who live in matrilineal (mother focused) social groups. Unlike the situation with dogs, we have not substantially altered anything about their social behavior until fairly recently. Again, unlike dogs, when we started to purpose-breed cats to develop cat breeds/breed fancy, we focused on changes in color, coat texture, coat length, tail or ear shape, an so on, not on enhancing specific jobs that different breeds do, as is the case with dogs. It is not surprising that the types of inappropriate aggression witnessed by clients differ from those seen in dogs and that they are understandable given the evolutionary context of feline social systems and the developmental context of sensitive periods. This is one of the reasons that it is often difficult for clients to understand—or even to recognize—intercat aggression. When complaints about feline elimination do not resolve with routine care and intervention there is a high probability that the elimination issues are interwoven with those involving intercat aggression. A complete history, including a viewing of family photographs and a video-tour of the cats’ ‘normal’ interactions will allow the clinician to understand these co-morbid interactions.

INTERCAT AGGRESSION

Normal aggression between cats is common only if the cats are toms. In most wild, feline social systems, few males mate with most of the females. The skewed sex ratio in the breeding population is induced and maintained by vigilance and aggression on the part of the males. There is an additional olfactory component of spraying and non-spraying marking that contribute to the aggression and relative “status.” The aggression exhibited by males in these circumstances is classic and involves flattened ears, howling, hissing, piloerection, threats using eyes, teeth, and claws and combat. Early neutering (prior to 12 months of age) decreases or prevents fighting by 90%. It is not clear if very early spaying and neutering programs would further reduce this, but given the hormonal facilitation of the aggression one would hypothesize that this would be the case.

That said, true intercat aggression—which is far more common and more likely than is territorial aggression, with which it is often confused—is pathological and is more commonly based on conflicts within social hierarchies than it is with sex. Cats begin to become socially mature some where between 2 and 4 years of age. At this time, some cats may begin to challenge others. Problems arise when one cat will not accept lack of engagement by another cat. Responses include passive aggression (staring and posturing), active aggression, and marking. Cats that consider themselves as more equal are less likely to participate in overt aggression - expect covert aggression (See Table 1 for a sample format by which to understand the variants of this form of aggression). Intercat aggression is extremely complex, often subtle, and under-appreciated.

Cats that are afraid of other cats can be spontaneously afraid of them or be afraid because they have been attacked, and may develop fearful behavior or fear aggression as sequelae. Co-morbidity of diagnoses should alert the client or clinician to explore which came first.

Table 1. Heuristic Model for Thinking About Phenotypic Patterns of Feline Aggression:

Potential Axes:

- Overt v. covert aggression
- Active v. passive aggression
- Offensive v. defensive aggression

Sample Scenarios:

- Overt, passive, offensive aggression: confident cat staring when another enters room
- Overt, passive, defensive aggression: less confident cat leaving room or backing up and withdrawing into smaller space, tail tucked vocalizing
- Covert, passive, defensive aggression: vanquished or less confident marking with mystacial glands in boundary areas or areas from which cat had been displaced
- Covert, active, offensive aggression: vanquished or less confident marking with urine or feces in boundary areas or areas from which cat had been displaced
- Overt, active, offensive aggression: chase and attack using teeth and accompanied by vocalization by resident cat toward new cat in environment
- Overt, active, defensive aggression: attack or response using hitting and or swatting while leaning back or avoiding further pursuit
- Covert, active, defensive aggression: withdrawal and marking of restricted area by victim cat
- Covert, passive, offensive aggression: displacement or theft of “bully” or higher ranking cat’s toys, bed, food, or hidden copulations (?), accompanied by non-elimination pheromonal marking

Cats that react as if there is a challenge about social status when there is none are reacting inappropriately and out-of-context. If there is a challenge (staring, blocking, hackles up, hissing, swatting, growling, etc.) of any kind, a reaction might be appropriate, but it is important to remember that as for people, many normal social behaviors in cats have rules. If one cat responds to another cat's stare or approach by leaving, tracking that cat down and becoming more overtly aggressive, this would be an inappropriate response. Most aggression in cats is far more subtle than it is in dogs, and because of this, may be more damaging to household situations.

Most intercat aggression about which clients complain occurs between housemates, and it may occur more commonly between different sex housemates, in contrast with dogs. Also, because feline systems are matrilineal, aggression may only become apparent after the loss of a 'matriarch' or cat fulfilling this role. It is not unusual for cats dogs to have lived in relative harmony together for 2 years before there are problems because the development of these problems reflects the intrinsic change that all social animals experience when the become socially mature.

Challenges can involve staring, vocalizing, or outright aggression. They can start with staring and escalate to aggression. Regardless, it is important to treat the problem as soon as it becomes apparent. The longer that the problem is allowed to persist, the worse the cats will get.

In profound cases of intercat aggression, the situation is not simple. This is especially true if multiple cats are in the household because cats form coalitions. This means that a cat who has been neutral to another specific cat may change his or her behavior depending on the addition or loss of new cats and the shifting of coalitions. Also, these relationships are not absolute. They change with age, health, and—most importantly—*behavioral context*. The manifestations of the relationships can be affected by the people who are present and by how those people interact with them. Some relationships apply only to feeding and sleeping orders. A cat who challenges one cat may not care about another cat in the household that, to all outward appearances, seems to act the same and be the same age and sex. Chances are they are not acting identically, and it is in the subtleties that the problems with the relationship occur.

Treatment of intercat aggression focuses keeping everyone safe, and on setting and maintaining a new social order where no individual is forced to sustain constant threats. Generally, reinforcement is given to the cat who is behaving most appropriately. Clients can most easily determine this by videotaping their cats and working with their veterinarian to understand what is ongoing between the cats. Identification of problem cats and those who are really normal is actually pretty easy if you can watch the cats in an unbiased manner. This is the advantage of videotape over real-time. The specifics of treatment follow.

First, please tell your clients to never physically punish these cats. All you will do is to raise their level of distress, and they might feel that they have to fight off the clients. Clients are often injuring when disciplining or separating fighting animals. You could make a bad situation worse by further causing the involved cats to be reactive and to learn that you are a threat.

Second, if at all possible, never reach between two fighting animals. Most people have good intentions and want to separate fighting animals to prevent injury to them, but if clients place their body parts between the animals, they may be accidentally injured. Rather, if the client knows that he or she has a problem with the cats, he or she should watch them like hawks any time they are together and keep cardboard, a broom, a bucket of water, a hose, or a blanket handy. These are all "remote control" items that can be used to separate the cats safely. If no small children, high-strung humans, or nervous animals are in the house, a loud noise, like that generated by a foghorn, can also help to separate animals for whom nothing else works, but this is drastic recourse and should be used cautiously.

Screaming by Humans, Particularly Young Humans, will Worsen the Situation

Generally, once the cats are apart, they start to calm down, and the aggressor can be moved to a location that is safer for everyone. Please remember that because of the unique reactivity of the feline posterolateral hypothalamus (PLH) and ventromedial hypothalamus (VMH), cats can stay reactive for 24 to 48 hours and that the clients may have to banish these cats while still protecting themselves. Most clients would find it easier to remove the victim, but this is not ideal. By removing the victim—instead of the aggressor—you may enhance the 'helplessness' of the victim in the eyes of the aggressor. You don't want to do this, if possible. Still, it is important to remember that any animal that is injured hurts and is frightened. These animals can bite without being malicious. Clients can avoid this by transporting victims and aggressors using blankets and boxes.

Environmental and social manipulation, classic passive and active behavioral modification, and pharmacological intervention (see Table 2) all have roles in treating intercat aggression.

MEDICATIONS

Benzodiazepines, while humanly abusable, can be excellent drugs for some cats who have joint elimination/aggression problems because of underlying nonspecific anxiety that results in a decrease in outgoing behavior in the affected cat. Clients should be advised to watch for any signs associated with hepatopathies, although these are extraordinarily rare. The exact mechanism of action of the benzodiazepines (eg, diazepam, chlordiazepoxide, clorazepate, lorazepam, alprazolam, and clonazepam) is poorly understood. At low dosages, benzodiazepines act as mild sedatives, facilitating daytime activity by tempering excitement. At moderate dosages they act as anti-anxiety agents, facilitating social interaction in a more proactive manner. At high

Table 2. Useful Medications (Brand Names are those in the US)

- Alprazolam (Benzodiazepine; Xanax) – for general calming, a panicolytic effect, and for encouraging affiliation: 0.025–0.050
- Amitriptyline (TCA; Elavil) – for the victim or aggressor with non-specific anxiety: 0.5–1.0 mg/ kg PO q 12–24 h
- Buspirone (NSA; BuSpar)–for the victim, only; may make more outgoing and situation resolves with some overt aggression: 0.5–1.0 mg/kg PO q 12–24 h
- Clomipramine (TCA; Clomicalm) – for the victim or aggressor with more specific anxiety: 0.5 mg/kg PO q 24 h
- Diazepam (Benzodiazepine; Valium) – for the victim, primarily, to make more outgoing and friendlier; for the aggressor if aggression is secondary to anxiety about interaction and increased friendliness will help: 0.2–0.4 mg/kg PO q 12–24 h
- Fluoxetine, paroxetine (SSRI; Prozac, Paxil)–for more specific anxieties involving outburst (fluoxetine) and social (paroxetine) anxieties: 0.5 mg/kg PO q 24 h
- Nortriptyline (TCA; Pamelor) – for the victim or aggressor with non-specific anxiety and sedation with amitriptyline: 0.5–1.0 mg/kg PO q 12–24 h

dosages they act as hypnotics, facilitating sleep. Ataxia and profound sedation usually only occur at dosages beyond those needed for anxiolytic effects. Note that the duration of action of the parent compound, diazepam, and its intermediate metabolite, nordiazepam (N-desmethyl diazepam) in cats is 5.5 h and 21 h, respectively.

Tricyclic antidepressants (TCAs) act to inhibit serotonin and norepinephrine (NE) re-uptake, and can be useful for some cats that spray, some who are averse to or anxious about their litter box, and cats who are experiencing anxiety about heir social situation. Drugs of choice include amitriptyline and its active intermediate metabolite, nortriptyline, and clomipramine. Knowledge of intermediate metabolites can be important: animals experiencing sedation or other side effects with the parent compound may do quite well when treated with the intermediate metabolite alone. For example, cats that become sedated or nauseous when treated with amitriptyline may respond well when treated with nortriptyline at the same dose since the former has two times the NE re-uptake effect of the latter.

Partial 5-HT$_{1A/B}$ agonists (eg, buspirone) have few side effects, do not negatively affect cognition, allow rehabilitation by influencing cognition, attention, arousal, and mood regulation, and may aid in treating aggression associated with impaired social interaction.

The SSRIs (fluoxetine, paroxetine, sertraline, and fluvoxamine) are derivatives of TCAs. These drugs have a long half-life, and after 2 to 3 weeks, plasma levels peak within 4 to 8 hours. Since these drugs act to induce receptor conformation changes—an action that can take 3 to 5 weeks—treatment must continue for a minimum of 6 to 8 weeks before a determination about efficacy can be made. Most of the SSRI effects are due to highly selective blockade of the re-uptake of 5-HT$_{1A}$ into pre-synaptic neurons.

As with all behavioral conditions, the earlier that intercat aggression is diagnosed and treated, the easier it is to treat and the better the outcome (meaning that clients have to live with fewer constraints). The key to treating any behavioral condition well is to communicate as much as we know in a manner that helps the client to participate as effectively as possible in the treatment.

BASIC TREATMENT CHECKLIST FOR CLIENTS TO TAKE HOME

1. **First, keep all cats involved in the intercat aggression separated at all times when not supervised.** If you able to identify the aggressor, the aggressor should be confined to the less desirable room (a spare bedroom, rather than your bedroom; a pen in the heated, well-lit basement; not in the kitchen where the dogs are fed). All other cats should have free-range. Again, in multicat households watch for changes in coalitions of the now re-configured social groups that may not be in the direction that you find helpful!

2. **Bell the cats with different sounding bells.** If the cats are loose you must be willing to supervise them. The bell will tell you when the aggressor is approaching and when the problem animals are close together. They can have a chance to approach each other **if and only if** you are confident that you can control them long-distance, and prevent any injury. Please remember—injury can be physical or behavioral. Of these, the behavioral injury may be worse for many cats who learn to live in constant terror. If you do not feel this way you must separate the cats in a manner that prevents over fighting and covert threats such as stares or urine marks.

3. **Choose an order in which to reinforce the cat based on identifying which cat is behaving the most appropriately. Remember—reinforcement is not about rewarding the pushiest, most 'dominant' cat.** It's about rewarding the cat who is most appropriate so that all the cats get the message that obnoxious behaviors are not rewarded, but calm, non-threatening ones are. When you reinforce the most appropriate cat you feed that cat first, give him or her attention first, give them access to the yard first, etc.

Reinforcing the chosen cat has active and passive components. First, separate the cats as discussed above. Second, enforce the concept that the cat being threatened has the right to exist by feeding him first, letting him out before the others (if they go out), giving him a treat or toy first, playing with first, grooming first, and so on.

You are not imposing a 'rank' order on these cats: instead, you are encouraging the normal types of social deference that would be exhibited by cats under normal conditions. By reinforcing an appropriately behaved cat you encourage the normal fluidity of the social system.

You can also more passively encourage the aggressor to understand that the victim has some status by allowing the victim sleep in a crate in your room, on a bed there, or on your bed, while the other cat is banished to a room or crate outside your room. This has nothing to do with beds and 'spoiling' and everything to do with the fact that access to preferred spots or to attention is a currency.

Regardless of how you decide to work with the cats, each cat needs daily individual attention. The cat that is being reinforced should always get the attention first, in the presence of the other cat if this can be done quietly and without threats or overt aggression. If necessary, restrain the inappropriate cat using a harness.

In this world view, treatment is about both understanding the neurochemical changes that occur with learning and repeated exposure, and about becoming humane. To do this, we must begin to see the world from the cat's point of view, which minimally requires that we let go of labels which may say more about us and our need, than they do about the behavior. The situation with intercat aggression demonstrates why we need to be more mindful of terminology, issues, and approaches which can inadvertently do more harm than good.

4. **Use harnesses with cats, if they are going to be together.** This gives you a quick way to intervene if you need it while gradually reintroducing them to each other when there is no attention being given. For example, watch TV while they both sit quietly, secured at a distance where they can see each other, but not lunge, and connect. If the cat that has been problematic stares at the cat you are trying to reinforce, gently turn his head away from the other cat and towards you so that he can take his cues from you. If the cat that you are trying to reinforce stares at the other, ignore him or her if the other cat doesn't react. If the other cat does react, interrupt them by asking them to look at you. If this does not work or if the aggression intensifies remove the most aggressive cat and banish him or her. If the cat that you are trying to reinforce stares at the other cat and the other cat looks away, reward them both with food treats—that is exactly the type of fluid and flexible behavioral relationship you are trying to reinforce.

5. **Anti-anxiety medications may help some cats that otherwise are not able to succeed in this program.** Please remember, if it's decided that medication could benefit your cat, you need to use it **in addition** to the behavior modification, not instead of it. Newer treatments involving a synthetic analogue of feline cheek gland secretions (eg, pheromones like Feliway™) show some promise for spraying that either has recently started and is related to the introduction of a new individual (human or animal), or to disruptions in the colony scent. Few excellent studies have been conducted, and the need for such studies is more critical in this situation than in those involving some oral medications because the mechanism of action is unknown, but appears to be relatively general. One peer-reviewed study that has examined the use of Feliway for the treatment of spraying, found that in many cases there was a statistically significant reduction in spraying, but few to no cats stopped spraying all together without the additional of behavioral modification. In some cases the concomitant use of pheromonal agents and anti-anxiety medications may produce a quicker resolution than would be produced by either alone.

COMBINING MEDICATIONS FOR MAXIMAL EFFECTS

Karen L. Overall, MA, VMD, PhD, Diplomate ACVB,
ABS Certified Applied Animal Behaviorist
Center for Neurobiology and Behavior
School of Medicine, University of Pennsylvania,
Philadelphia, PA

RATIONALE

The addition of psychotherapeutic agents to routine behavioral treatments, such as behavioral and environmental modification, has lead to better and faster treatment outcomes. In addition to facilitating better treatment of domestic animals and humans, psychopharmacological developments have permitted hypotheses about underlying mechanistic pathology to be tested. Mere treatment of non-specific behavioral complaints and signs is outdated (eg., treat barking by cutting the vocal cords) and has been replaced with an approach that includes ensuring that you meet the criteria for diagnosis, prior to treatment, followed by treatment that addresses the specific mechanism underlying the neurochemical contribution to the pathology.[1]

The use of medication should occur and is most effective as part of an integrated treatment program. There is no substitute for the hard work involved in behavior modification; however, some medications may be able to make it easier to implement the modification.[2,3,4] Those seeking 'quick fix' solutions will doubtless be disappointed: inappropriate drug use will not alter the processes or environments that produced the behavior. While medication, alone, may render an animal globally less anxious, if the animal is still being provoked by social or physical environmental stimuli the benefit of treatment with medication will be minimized. It is partly this facile and inappropriate use of medication that has led many practitioners to falsely believe that medication does not work. Nothing could be further from the truth: the newer serotonin-affecting medications, protective nutraceuticals, and enhanced dietary regimes have a huge potential improve life for troubled pets and their distressed people. In fact, rational drug use should now minimally be considered part of basic humane treatment of our patients.

ADVERSE EFFECTS

The neurotransmitters affected by behavioral medications are acetylcholine, serotonin, norepinephrine (noradrenaline), dopamine, gamma amino butyric acid (GABA), and excitatory amino acids. Common adverse effects of psychotherapeutic drugs are usually caused by a blockage of the muscarinic acetylcholine receptors, which have diffuse connections throughout the brain. These 'common' side effects are actually quite rare and generally manifest themselves as transient changes in GI function or heart rate. If these side effect ARE NOT transient, clients need to understand that their pet may be experiencing a serious problem. For this reason, it is important to encourage clients to help monitor both their animal's response to the medication and any side effects that they may have. Clients can easily learn to take pulse rates. Slight increases in pulse rate when treated with any medications affecting norepinephrine—as most the anti-anxiety agents do—are not worrisome. Huge, sustained increases are problematic. If clients know that their dog's resting heart rate is 65 bpm and with medication this changes to 150 bpm, they can immediately bring this change to their vet's attention. Likewise, if the increase is minor (65 to 75 bpm) they can relax and not worry. Educated clients will monitor their pets better, will be more willing to use medications and behavior modification appropriately, and will also be less likely to take the veterinarian's time needlessly. While many benzodiazepines (BZ) can be sedative, newer BZs have decreased sedative effects. Still, because dogs and cats, like humans, can experience a huge range of effects when given a BZ, clients should be encouraged to give any BZ when they can monitor the patient. This practice is extremely helpful in ensuring that we recognize animals with atypical or serious sedative responses so that we can find more appropriate medications with which to treat them.

Most behavioral drugs are metabolized through renal and hepatic pathways so knowledge of baseline values is essential. That said, these medications can be used in compromised animals if adjustments are made and the animal is monitored behaviorally and biochemically.

All psychotropic medications can interact with other medications. For example, use of most anti-anxiety agents will cause thyroidal values, whether or not supplementation is involved, to read falsely low. Many of serotoninergic agents are thought to lower seizure thresholds and so are recommended with caution in patients treated with seizures. That said, there is now evidence in both the human and canine literature that anxiety may lower seizure thresholds and so treatment of the anxiety may allow the patient to successfully decrease the amount of seizure medication needed.

EFFICACY AND MECHANISM OF ACTION

It is important for clients to understand that newer, more specific, more efficacious drugs have a relatively long lag time between initiation of treatment and apparent changes in the patient's behavior. This delay is due to the mechanism of action of the tricyclic antidepressants (TCAs) and the selective serotonin re-uptake inhibitors (SSRIs), which employ second messenger systems to alter transcription of receptor proteins.

Serotonin

Serotonin (5-HT) receptors are all G-protein-coupled receptors. There are 14 identified classes of serotonin receptors. The 5-HT$_1$ receptors are linked to the inhibition of adenylate cyclase and affect mood and behavior. Presynaptic 5-HT$_{1A}$-receptors predominate in dorsal and median raphé nuclei; post-synaptic 5-HT$_{1A}$-receptors predominate in limbic regions (hippocampus and septum) and some cortical layers. Activation of pre-synaptic receptors by agonists results in decreased firing of serotonergic neurons leading to transient suppression of 5-HT synthesis and decreased 5-HT release; activation of post-synaptic receptors decreases firing of post-synaptic cells. These are 'thermostatic' effects, not integrated outcomes of receptor activation. The overall effect depends on regulation of second messengers (cAMP, Ca^{2+}, cGMP, IP_3) and their effects on protein kinases which then alter neuronal metabolism and receptor protein transcription.[5] The subclasses of 5-HT receptors vary in their affects. 5-HT_{1A} receptors affect mood and behavior. 5-HT_{1D} receptors affect cerebral blood vessels and appear to be involved in the development of migraine. These last two classes of receptor subtypes are the primary focus of many behavioral drugs. Urinary excretion of 5-HIAA (5-hydroxy indoleacetic acid) is a measure of 5-HT turnover and has been used to assess neurochemical abnormalities in human psychiatric patients, and has potential in this regard for veterinary behavioral medicine.

Nutraceuticals

Nutraceuticals designed to augment 5-HT or 5-HT supplements may not engender the same response as to pharmacologic agents because 5-HT does not pass easily through the blood–brain barrier (BBB), and instead requires the help of a transport protein. This transport protein is also used to move other amino acids across the BBB, and so, even if 5HT-containing substances are absorbed unchanged from the GI tract, they may be excreted depending on the pharmacodynamics of the other amino acids present.[6]

Noradrenaline/Norepinephrine (NE)

The most prominent collection of noradrenergic neurons is found in the *locus coeruleus* of the gray matter of the pons and in the lateral tegmental nuclei. There is also a cluster in the medulla. NE has been postulated to affect (1) mood [NE decreases in depression and increases in mania], (2) functional reward systems, and (3) arousal.

Dopamine

The distribution of dopamine in the brain is non-uniform, but is more restrictive than that of NE. Dopaminergic nuclei are found primarily in (1) the *substantia nigra pars compacta,* which projects to the striatum and is largely concerned with coordinated movement; (2) the ventral tegmental area, which projects to the frontal and cingulate cortex, *nucleus acumbens*, and other limbic structures; and (3) the arcuate nucleus of the hypothalamus, which projects to the pituitary. A large proportion of the brain's dopamine is found in the *corpus striatum*, the part of the extrapyramidal system concerned with coordinated movement.

Dopamine is metabolized by monamine oxidase (MAO) and catechol-O-methyl transferase (COMT) into dihydroxyphenyl acetic acid (DOPAC) and homovanillic acid (HVA). HVA is used as a peripheral index of central dopamine turnover in humans, but this use has been little explored in veterinary medicine. All dopaminergic receptors are G-protein-coupled transmembrane receptors. The D_1 receptors exhibit their post-synaptic inhibition in the limbic system and are affected in mood disorders and stereotypies. The D_2, D_3, and D_4 receptors are all affected in mood disorders and stereotypies. Excess dopamine, as produced by dopamine releasing agents (amphetamines and dopamine agonists, like apomorphine) is associated with the development of stereotypies. Because of this, and because acepromazine is a neuroleptic agent that scrambles memory but does not prevent or treat anxiety, ACEPROMAZINE SHOULD NEVER BE USED AS A BEHAVIORAL MEDICATION OR AS A TREATMENT FOR STORM PHOBIAS.

Gamma Amino Butyric Acid (GABA)

GABA, the inhibitory neurotransmitter found in short interneurons, is produced in large amounts only in the brain and serves as a neurotransmitter in ~30% of the synapses in the human CNS. The only long GABA-ergic tracts run to the cerebellum and striatum. GABA is formed from the excitatory amino acid (EEA) glutamate via glutamic acid decarboxylase (GAD), catalyzed by GABA-transaminase (GABA-T) and destroyed by transamination. There are two main groupings of GABA receptors: $GABA_A$ and $GABA_B$. $GABA_A$ receptors, ligand-gated ion channels, mediate post-synaptic inhibition by increasing Cl^- influx. Barbiturates and benzodiazepines are potentiators of $GABA_A$; however they do so by increasing the amount of time channels remain open - a relatively nonspecific change. It is for this reason why these are NOT suitable behavioral medications, and why one is more likely to get a sedated, rather than a less anxious dog, when the dog is treated with phenobarbital for behavioral reasons. $GABA_B$ receptors are involved in the fine-tuning of inhibitory synaptic transmission: presynaptic $GABA_B$ receptors inhibit neurotransmitter release via high voltage activated Ca^{++} channels; postsynaptic $GABA_B$ receptors decrease neuronal excitability by activating inwardly rectifying K^+ conductance underlying the late inhibitory post synaptic potential.

GABA also has a variety of tropic effects on developing brain cells. During ontogeny GABAergic axons move through areas where other neurotransmitter phenotypes are being produced, and so may be related to later monoaminergic imbalances. The extent such ontogenic effects are relevant for behavioral conditions is currently unknown but bears investigating.

EAAs (Glutamate, Aspartate, and, Possibly, Homocysteate)

EEAs have a role as central neurotransmitters and are produced in abnormal levels in aggressive, impulse, and schizophrenic disorders. The main fast excitatory transmitters in the CNS are EEAs. Glutamate, widely and uniformly distributed in the CNS, is involved in carbohydrate and nitrogen metabolism. It is stored in synaptic vesicles and released by Ca^{2+} dependent exocytosis, so calcium channel blockers may affect conditions associated with increased glutamate. Both barbiturates and progesterone suppress excitatory responses to glutamate. Pre-synaptic barbiturates inhibit calcium uptake and decrease synaptosomal release of neurotransmitters, including GABA and glutamate.

Roles for Neuronal Stimulation, Synaptic Plasticity, and Receptor Protein Transcription and Translation

What makes TCAs and SSRIs special and why are they so useful for anxiety disorders? The key to the success of these drugs is that they utilize the same second messenger systems and transcription pathways that are used to develop cellular memory or to "learn" something. This pathway involves cAMP, cytosolic response element binding protein (CREB), brain derived neurotrophic factor (BDNF), NMDA receptors, protein tyrosine kinases (PTK), particularly Src, which regulate activity of NMDA receptors and other ion channels and mediates the induction of LTP (long-term potentiation = synaptic plasticity) in the CA1 region of the hippocampus.

There are two phases of TCA and SSRI treatment: short-term effects and long-term effects. Short-term effects result in a synaptic increase of the relevant monoamine associated with re-uptake inhibition. The somatodendric autoreceptor of the pre-synaptic neuron decreases the firing rate of that cell as a thermostatic response. Regardless, there is increased saturation of the post-synaptic receptors resulting in stimulation of the α-adrenergic coupled cAMP system. cAMP leads to an increase in PTK as the first step in the long-term effects. PTK translocates into the nucleus of the post-synaptic cell where it increases CREB, which has been postulated to be the post-receptor target for these drugs. Increases in CREB lead to increases in BDNF and tyrosine kinases (eg, trkB) which then stimulate mRNA transcription of new receptor proteins. The altered conformation of the post-synaptic receptors renders serotonin stimulation and signal transduction more efficient.

Knowledge of the molecular basis for the action of these drugs can aid in choosing treatment protocols. For example, the pre-synaptic somatodendritic autoreceptor is blocked by pindolol (α-adrenoreceptor antagonist) so augmentation of TCA and SSRI treatment with pindolol can accelerate treatment onset. Long-term treatment, particularly with the more specific TCAs (eg, clomipramine) and SSRIs, employs the same pathway used in LTP to alter reception function and structure through transcriptional and translational alterations in receptor protein. This can be thought of as a form of in vivo "gene therapy" that works to augment neurotransmitter levels and production thereby making the neuron and the interactions between neurons more coordinated and efficient. In some patients short-term treatment appears to be sufficient to produce continued "normal" functioning of the neurotransmitter system. That there are some patients who require life-long treatment suggests that the effect of the drugs is reversible in some patients, further illustrating the underlying heterogeneity of the patient population considered to have the same diagnosis.

MONITORING

Monitoring of side effects is critical for any practitioner dispensing behavioral medication. The first tier of this involves the same tests mandated in the pre-medication physical and laboratory evaluation. Age-related changes in hepatic mass, function, blood flow, plasma drug binding, et cetera cause a decrease in clearance of some TCAs, so it is prudent to monitor hepatic and renal enzymes annually in younger animals, biannually in older, and always as warranted by clinical signs. Adjustment in drug dosages may be necessary with age.

It is generally preferable—but not necessarily required—to withdraw most patients from one class of drug before starting another. For most medications this is done so that one can be sure which medication is associated with any noted change in behavior. When changing between SSRIs and MAOIs a washout period is mandatory because of the potential for serotonin syndrom.......the recommended drug-free time in humans and dogs is two weeks (2 + half-lives: the general rule of thumb for withdrawal of any drug).

POLYPHARMACY

Oddly, because of the cytochrome systems that metabolize medication, it may be safer for the animal and more efficacious in terms improvement of the condition to combine medications. When medications are combined, knowledge of side effects and specific mechanisms of action is essential. That said, medications within related classes can usually be combined and such combination can allow a lower dose of each of the medications to be given. Medications of different classes can often be combined, if the potential side effects are compatible, and if the practitioner has a clear understanding of what conditions will or should respond to each medication.

For example, tricyclic antidepressants (TCAs) and selective serotonin reuptake inhibitors (SSRIs) can be combined with each other, and, if needed, with other medication within the class. For this to be done rationally, however, understanding potentiation of effect and side effects is essential. TCAs generally exert their largest effects on serotonin (5-HT) receptors, norepinephrine (NE) receptors, and some histaminic receptors (H). Additionally, they can have effects on some of the adrenergic receptors. The latter is important primarily when premedication for anesthesia is involved. SSRIs primarily affect 5-HT receptors, and most have an affinity for the 5-HT1a subtype receptor. Additionally, there are some weak effects on NE receptors. TCAs that are less specific (eg, amitiptyline) and SSRIs that are more specific (eg, fluoxetine) will be the easiest to combine since the overlap effects on the receptor will be less, while the generalized sensitization of the receptors in the class will be augmented.

Combination treatment allows the clinician to use the lower end of the dosage for both compounds which minimizes side effects while maximizing efficacy. Furthermore, benzodiazepines can be used to blunt or prevent acute anxiety-related outbursts on an as needed basis in patients for whom daily treatment with a TCA or an SSRI is ongoing. Together, the combination of benzodiazepines and TCAs/SSRIs may hasten improvement and prevent acute anxiety-provoking stimuli from interfering with treatment of more regularly occurring anxieties.

When stopping a drug, weaning is preferred to stopping abruptly.[7] A model for how to do this is found below.[7] Weaning minimizes potential central withdrawal signs, including those associated with serotonin discontinuation syndrome[8,9] and allows determination of the lowest dosage that is still effective. If patients are withdrawn fully, rather than weaned from medication, they may not have the same response to the medication that they had originally. Patients with discontinuation or cessation syndrome become moody and lethargic, but these effects usually pass within a week. If they do not, re-assessment of the wisdom of stopping medication is warranted. Medications that have the longest $t_{1/2}$ of intermediate metabolites (eg, fluoxetine) are less likely to cause problems when withdrawn quickly than are those with short half-lives or no functional intermediate metabolites (eg, paroxetine). However, SSRIs that have the greatest in vivo reuptake capabilities (eg, paroxetine) may be more at risk for involvement in serotonin syndrome. Long-term treatment may be the rule with many of these medications and conditions, but maintenance may be at a considerably lower level of drug than was prescribed at the outset. The only way the practitioner will discover if this is so is to withdraw the medication slowly.

Because of these patterns, it is best NOT to withdraw animals from medication prior to anesthesia, but instead to adjust the pre-medication sedation so that fewer interactions, particularly of the adrenegic variety, can be expected.

Finally, many animals appear to stop responding to medication. Staying the course may be the best decision in some of these cases because the CPY system is an inducible one, and multiple medication changes may just make the animal more—not less—refractory.[10] Additionally, there is a huge range of genetic polymorphisms that determine how this system acts.[11] These are all poorly understood in dogs because they have been so little investigated. However, given their importance in human psychiatry we'd be remiss if we didn't start to believe that such patterns may no be independent of disease state.

Polypharmacy can be safe, rational, and cheap, and can save animals' lives. But this is an area that really requires an understanding of how these medications act. Fortunately, the functioning of these medications is easy to understand.

Sample Combinations[12]:

- amitriptyline (TCA) + fluoxetine (SSRI)
- amitriptyline (TCA) + fluoxetine (SSRI) + alprazolam (BZ)
- amitriptyline (TCA) [anxiety] + alprazolam (BZ) [panic]
- fluoxetine (SSRI) [anxiety] + alprazolam (BZ) [panic]
- clomipramine (TCA - relatively specific) [anxiety] + alprazolam (BZ) [panic]
- clomipramine (TCA - relatively specific) [anxiety] + diazepam (BZ) [panic / phobias] - could be pretty sedating
- amitriptyline (TCA) [anxiety] + diazepam (BZ) [panic/ phobias] - could be pretty sedating
- selegiline (MAO-I) (cognitive dysfunction) + diazepam (BZ) [panic / phobias]
- selegiline (MAO-I) (cognitive dysfunction) + alprazolam (BZ) [panic]
- paroxetine (SSRI) (social anxiety) + alprazolam (BZ) [panic / appetite stimulation in cats]

Table 1. Half-lives of Parent Compounds and Intermediate Metabolites of Target Benzodiazepines in Humans[7]

Parent Compound	$t_{1/2}$ Parent Compound	$t_{1/2}$ Intermediate Metabolite	Overall Duration of Action
Triazolam	2–4 h	2 h	Ultra short: 6 h
Oxazepam	8–12 h		Short: 12–18 h
Alprazolam	6–12 h	6 h	Medium: 24 h
Diazepam	24–40 h	60 h	Long: 24–48 h
Clonazepam	50 h		Long: 24–48 h

Table 2. Duration of Action of Parent Compound, Diazepam, and its Intermediate Metabolite, Nordiazepam (N-Desmethyl Diazepam), Which is Responsible for Most Sedation, in Selected Domestic Animals[7]

Species	Diazepam	N-desmethyl diazepam
Horse	24-48 h	51-120 h
Cat	5.5 h	21 h
Dog	3.2 h	3-6 h

Table 3. Relative Effects of TCA Parent Compounds and Intermediate Metabolites on NE and 5-HT re-uptake[7]

Parent Compound	Intermediate Metabolite	NE	5-HT
Desipramine		0	5
Imipramine	desipramine	+++	0
Amitriptyline	nortriptyline	0	0
Nortriptyline		0	0
Clomipramine	n-desmethyl clomipramine + clomipramine*	0	+++

* Does not include the specific effect of the intermediate metabolite as a selective serotonin reuptake inhibitor (SSRI)

Table 4. "Gestalt" of TCA and SSRI use based on $t_{1/2}$ of parent compounds and active intermediate metabolites, relative effects on NE and 5-HT, and extrapolations from multi-center human studies (7)

Diagnosis / Type of Condition	First Drug of Choice
Narcolepsy	Imipramine
Milder, relatively nonspecific anxieties	Amitriptyline
Milder, relatively nonspecific anxieties with avoidance of sedation	Nortriptyline
Social phobias / anxieties concerning social interaction	Paroxetine
Panic / generalized anxiety	Sertraline
Outburst aggression / related anxieties	Fluoxetine
Ritualistic behavior associated with anxiety, including OCD	Clomipramine

Table 5. Algorithm for Treatment Length and Weaning Schedule[7]

- Treat for as long as it takes to begin to assess effects:
  - 7–10 days for relatively non-specific TCAs
  - 3–5 weeks minimum for SSRIs and more specific TCAs

PLUS

- Treat until "well" and either have no signs associated with diagnosis or some low, consistent level:
  - Minimum of another 1–2 months

PLUS

- Treat for the amount of time it took you to attain the level discussed in (2) so that reliability of assessment is reasonably assured:
  - Minimum of another 1–2 months

PLUS

- Wean over the amount of time it took to get to (1) or more slowly. Remember, if receptor conformation reverts it may take 1+ months to notice the signs of this. While there are no acute side effects associated with sudden cessation of medication, a recidivistic event is a profound "side effect". Full-blown recidivistic events may not be responsive to re-initiated treatment with the same drug and, or the same dose:
  - 7–10 days for relatively non-specific TCAs
  - 3–5 weeks minimum for SSRIs and more specific TCAs

TOTAL: Treat for a minimum of 4–6 months

HOW TO PET DOGS, HOW TO TEACH DOGS TO RELAX, AND WHY THIS MATTERS

Karen L. Overall, MA, VMD, PhD, Diplomate ACVB,

WHAT IS MEANT BY 'DEFERENCE' AND WHY IT IS IMPORTANT

Dogs have social systems that are very similar to those of humans. They live in extended family groups, they have extensive and extended parental care, will work as a group or a family to help care for the offspring, nurse their young prior to feeding them semi-solid, then solid, food, use play as one form of developing social skills, communicate extensively vocally and non-vocally, and—most importantly—dogs have a social system that is based on deference to others and that governs different roles in different contexts.

Fights for status or control are notoriously **rare** among wild canids, including wolves. Except in what humans perceive to be abnormal social conditions, most human social relations are structured by negotiation and deference to others, rather than by violence. Deference-structured hierarchies mean that the individual to whom others defer may differ depending on the contextual and social circumstances. Status is always relative and is characteristic that is conferred by members of the social group, not taken by force. Status is also not absolute. In the human situation, a child may defer to his parents' requests, but then be the leader on the playground to whom other children defer. Dogs are similar.

Much has been written about dogs viewing their human families as their packs. It's important to remember that "pack" is just a word to describe a canid social grouping, like "pod" described a group of whales, and "gaggle" describes a group of geese. The problem for our dogs is that there is a value judgment within the word. Humans have wrongly attributed a value structure and judgment to the word "pack" and then assumed dogs viewed us as part of theirs. While the pack comparison is not exact, dogs are social and generally will look to their people for guidance. Dogs often become problems when they cease to do this, or if they never do this, or if they cannot do this.

All social animals create some form of rule structure. While cats have very different social systems than do dogs and people, it's that rule structure that allows cats to respond to this program, as well as dogs, although it is primarily written for dogs. The rule structure is what allows all social animals to communicate with each other. Clear communication is essential in social animals because it avoids an inefficient and potentially dangerous use of time (eg, fighting). Because dogs are so similar to us in so many ways, and so frequently look like they are hanging on our every word, we assume that they are complying with **our** rule structure and all its nuances. Puppies actually need guidance in how to do comply with or negotiate our wishes, and problem dogs need to have a consistent, benign, kind rule structure explicitly spelled out for them: if the dog knows a consistent rule or behavior that will get the attention of their people, the dog will then be receptive to guidance. This is a form of discipline, but we need to note that people often confuse discipline and violence or abuse. Any use of any behavioral modification program must focus on relaxation and **MUST be executed without violence or physical abuse**, or you will earn your pet's distrust. In fact, for most dogs, withdrawal of attention is a far more profound correction than is physical abuse. Abused dogs or those consistently mismanaged with physical punishment will either learn to over-ride the punishment, or learn to seek it, since it may be the most common contact that they get.

Physical punishment includes leash or collar "corrections" using a 'choke' collar or a prong collar, hitting the dog, walking the dog into a pole or tree to make him pay attention, and tying the dog so that he cannot move. If these punishment techniques sound abusive, it's because most often they are. The true definition of punishment doesn't require pain: it requires a stimulus sufficiently powerful that the undesirable behavior is abandoned by the dog **with the subsequent result** that the probability of the dog exhibiting the behavior **in the future** is lowered. The emphasized parts of this sentence are important because unless these conditions are met the dog is not being 'punished'—they're being injured mentally and, perhaps, physically. By far, the more favorable way to handle undesirable behaviors—and we have to remember that we, as humans, have taste preferences that are different from those of dogs—is to prevent them. If they cannot or were not prevented, rather than punishing the dog we should ignore the behaviors and so withdraw any attention associated with them. Finally, we should be clear to the dog and tell the dog what behaviors **will** get the dog attention. It's utterly unfair to the dog to have him try to 'guess' what it is that will get you to stop yelling at him and start loving him, yet these are the circumstances to which many dogs are reduced. These three steps are what practicing deference is all about.

The intent of behavior modification using relaxation techniques is to set a baseline of good behavioral interaction between the client and dog, and to teach the dog that if he or she consistently is calm, quiet, attentive, and defers to his or her people, attention and rewards will follow. In turn, the people learn to have realistic expectations for their pet and to signal clearly, calmly, and kindly to their pet. This type of protocol also gives the clients permission to **not** be angry at the dog—instead, they can walk away. To have a great relationship with a dog it is not necessary to control the dog's every move. The best dog–human relationships are the ones where clear signaling is involved—and good play almost guarantees this—and ones where both dog's and human's needs are respected and met.

These goals are accomplished in a safe, kind, passive manner, and it is tougher to do this than clients frequently acknowledge. The reason for this is as follows: if the clients are talking, reading, or watching TV and the dog comes up to them and rubs, paws, or leans against them, the clients usually passively reach out and touch or pet the dog. The dog controlled that entire interaction. The traditional way to view this is to see it as a contest with the score as: dog, 1; human, 0. This competitive, confrontational approach to working with dogs injures our relationship with them and often ends with injuring the dog behaviorally or physically. In the example given, the dog controlled the interaction—with default 'permission' by the humans—and the dog learned that if he or she was persistent they could get attention, regardless of the form of the attention. However......something more important happened here. If the dog is uncertain, anxious, concerned, or worried about the rules of the interaction.......getting attention from the people in this context made all of those problems worse. Humans need to understand that they are **always** signaling to the dog whether they intend to or not and that dogs read non-verbal signaling better than people do. Given this, humans must assess if their response is rewarding the behavior that they think it is. Here's a hint: if the dog is getting peskier or more worried, the human is not reading the signaling situation correctly. This objective can be achieved by putting their butt on the ground for just a second and looking at the human.

THE ROLE FOR SITTING

Dogs naturally sit as part of their species-typical repertoire of deferential behavior. Sitting is a 'stop' signal that takes the dog out of the active interaction and allows him or her to focus on matters at hand. Dogs ask questions to get information, and sitting can be a form of asking a question. If you watch young puppies, they will back away from an interaction and sit at the periphery when they are uncertain. Their uncertainty is either addressed by observation, or because a dog detaches himself of herself from the group and approaches the puppy to provide the needed information. Sitting—a classic deferential behavior that all dogs understand—allows dogs to focus on their human and to communicate efficiently and accurately. Having the dog sit is not about "control" or "mastery" of the dog—it's about increasing the chance that you can signal clearly to the dog and that you have the dog's undivided attention while signaling. Because dogs naturally defer to other dogs by sitting or lying down and looking at them, we can have them defer to us and be ready to take their cues from our signals by having the dog sit.

The sit does not have to be and should not be prolonged at first. It can be as short as seconds as long as the dog's butt is on the ground and the dog is looking quietly at the person. Even a 5-week-old puppy can sit—butt flush to the ground for a few seconds—and look you, even if they are wiggle worms. Pups can even learn to sit and attend to the client (look at them for cues, make eye contact, look happy and attentive while being quiet) in exchange for a food treat. As soon as the puppy sits, the person should say "Good girl (boy)!" and give a tiny treat of something special. Simply as soon as the dog's butt is on the ground, praise the dog and tell him he is brilliant, and give the treat. Dogs can also be petted if and only if this will not arouse and distract them and cause them to rise.

Quite simply, the deferential behavior of sitting provides dogs with a rule that allows them to seek, and then take, guidance and help. **All** dogs should learn this and **no** dog is too old to learn this.

A few tips on how to look at a dog while communicating may be useful.

1. **Don't** "stare down" dogs. Normal dogs will look away, anyway, if you look scary enough, and troubled dogs will think you are a threat— because you are—and their anxiety or aggression will worse.
2. **Do** look at the dog or cat. Looking someone directly in the eye is the best way to ensure that you are communicating well. Looking at a dog is different than staring. When you stare you don't move your eyes, you stiffen the muscles in your face, and your pupils likely dilate. This is a threat. Looking is much more relaxed and is important for clear communication in all mammals with decent eyesight.
3. If when you just casually look at the dog or cat he begins to be aggressive, divert your gaze so that you can keep them in view with your peripheral vision, while not making direct eye contact. This will often lessen any aggression. It is always a horrible idea to try to "out-stare" any aggressive animal.

TEACHING RELAXATION

Any protocol designed to teach dogs to relax as part of a treatment program can also be used as a **preventative** program for puppies and kittens, dogs and cats. **The single biggest mistake vets and trainers make is to forget about the preventative use of these types of programs.**

Simply put, the purpose of this particular **Protocol for Relaxation** is to teach the dog or cat to sit and stay while relaxing in a variety of circumstances. The cat or dog cannot progress to learning how to relax unless he or she trusts the human enough to sit and attend to them when requested to do so.

It's the rare dog who will not sit and then look to another individual for instructions or information about what is to come next. *However*—and this is a **huge** *however*—dogs can sit and look at you, **and still be terrified**. If you reward the dog or cat when he or she is exhibiting any behavior other than a relaxed, calm pose, you have just inadvertently also rewarded their anxiety, fear, distress...whatever. This is **not** what you want to do.

Starting out — roles for spontaneous reward and using the 'shaping' technique: So, before you even start this program, learn what a relaxed facial and body expression in your pet looks like. Practice rewarding this expression. If you can only get the animal to look calm and relaxed for a few seconds at first, that's fine.....you can gradually expand the time they stay relaxed by rewarding the behavior every time it occurs and while it is continuing to occur.

Why do we wish to reward dogs only when they look progressively more relaxed? The amygdala is the region of the brain that is found at the anterior tip of the hippocampus. The main role of the hippocampus is to process associational learning. The main role of the amygdala is to regulate fear and to engender adaptive fear responses. These two regions are connected by a diffuse neuronal structure with projections to the frontal cortex. It should be clear how easy it is to reinforce and 'train' a fearful response given this organization. The frontal cortex, with the hippocampus, is the site of learning or—at the molecular level—long-term potentiation (LTP). Memories are stored via protein configuration changes that make new neurochemicals, new receptors, et cetera when these regions of the brain are stimulated over time. Consider how easy it would be to engender a fearful response that now becomes learned—with all of its associations—unless care is taken to avoid distressing the dog. Instead, we need to teach the dog that when he or she relaxes—when that relaxed and loose face appears, when he or she can take a deep breath—he or she will feel better. Dogs are cognitive, and can learn to learn, instead of learning to react, but they cannot do that without learning to relax first. Deep breathing and holding breath allows the dog to lower his or her heart rate and so diminishes the outward physical signs of arousal, diminution in pupil size indicates a physiological response to decreased arousal, and all of these add up to provide a learning situation that is not over-ridden by cortisol. We now believe that cortisol can act as a hormone response element (HRE). As such, it can block transcription of new proteins that would develop as part of learning. In short, very stressed and distressed dogs may comply with people's requests because of fear, but they cannot learn not to be fearful unless they can relax.

Often, because of endogenous factors or past experience it is difficult to get a 'relaxed look'. In such cases we should use successive approximation—reward a look that is less distressed. By using a learning technique called shaping you continually reward behaviors that are better approximations of the behavior you want. And.....**no shrieking at the dog or cat when they backslide**.......instead, you just ignore the anxious behaviors that are not going in the direction that you want (eg, more relaxed). For example, if—no matter what you do—the dog's eyes are popping out of his head and he's panting, just walk away and quit. This is **not** a contest or an endurance test. Then, when the dog spontaneously exhibits calm behaviors....maybe even before he goes to sleep..... reward **those** calm behaviors. Softly telling the pets that they are wonderful when they are already asleep is the least used trick to improve their behavior, but it works! Don't startle them, don't pet them, just quietly commend them.

For very, very anxious dogs, before you can even start a full relaxation program, you will have to spend a lot of time spontaneously rewarding the dog when he or she exhibits the relaxed behavior just in the context of everyday life. Only then, will that dog be able to move on to having their behaviors shaped in response to a request. After that, the dog can start the program, **but only after achieving an acceptable level of success where their calm behaviors are rewarded.**

Encourage clients to be gentle, but be consistent. Remind them that taking your anger or fear out on the dog will only make him or her worse. As soon as the dog responds and calmly sits, reward the dog, and continue. Never reward a dog that is growling, lunging, barking, shaking, or urinating.

Finally, please remember that the dog or cat will give you lots of cues about how they are feeling. Dogs are continually signaling information that people will find useful. In turn, they use human signals to adjust their own signaling and behavior. Dogs are cognitive and ask questions by offering behaviors. Take advantage of this and reward the most relaxed and informative behaviors. This program differs from other behavior modification programs because of the emphasis on these signals. We are rewarding the physical changes associated with relaxation and happiness and so will also reward the underlying physiological states associated with this (parasympathetic part of the autonomic nervous system). This means that if the dog is relaxed, his or her body is not stiff, his or her jaws hang relaxed and are not tense, his or her ears are alert or cocked, but not rigid, his or her head is held gently at an angle, and his or her eyes are calm and adoring, you will be rewarding the nervous system responses that help your dog to learn. If you mistakenly reward fear, tension, aggression, or avoidance, you will not make progress, and, over the long term, could do harm.

DEALING WITH AGGRESSION IN THE VETERINARY CLINIC

Kersti Seksel, BVSc (Hons), MRCVS ,MA (Hons) ,FACVSc (Animal Behaviour), Diplomate ACVB, CMAVA
Sydney Animal Behaviour Service
Seaforth, New South Wales, Australia

Dealing with an aggressive dog or cat is not fun for anyone concerned. It is stressful for the owner, the dog or cat, as well as the target of the aggressive response. When it happens during a veterinary visit, it is even more difficult to deal with as we are seen as the professionals who should be able to handle with the situation. We are the ones who should be able to prevent the aggressive response. It is one of the most difficult situations to handle calmly. It can be a very confronting experience yet veterinary staff may face this in practice on a regular basis.

The way that the situation is handled at the time will impact on the way the visit is perceived by the dog or cat, the owner, and the staff. It will also determine whether the visit is traumatic or a potentially dangerous experience (not only for the dog or cat, but also for the staff). However, if handled well this visit can also be the first step towards making the next visit less stressful and more pleasant for all concerned.

After all, as the profession that cares for animals, the aim of all staff should be to make each visit, especially the first visit of the dog or cat to the veterinary hospital, as stress free and pleasant as possible.

Many years ago veterinarians had to rely on brute force and sheer numbers (ie, staff members) to manage aggressive animals. The animals were forcibly held down and the procedure was carried out. Not only did the veterinary profession not have quick-acting sedatives or anesthetics, we also did not have the behavioral knowledge we have today. In addition, the maxim was that it was important not to let the animal "win."

Today, however, we now have many more humane ways of dealing with difficult pets. We recognize that most of these pets are stressed or anxious and veterinary medicine has advanced so that we have many more ways of helping these pets. It should no longer be necessary to manhandle or wrestle any dog or forcibly restrain any cat. These days there is little need for a visit to the veterinary hospital to be a traumatic experience: not for the dog or cat, the owner, or the veterinary hospital staff.

In addition, concern for the animal's welfare should be paramount.

Veterinarians also need to recognize that most pet owners see their pets as family members. As such the owners of these pets find it very distressing to see a member of their family handled in such a forceful manner.

A much better result can be achieved by working with the animal and the owner. By recognizing why the animal may be behaving in such a manner each veterinary visit should become a more pleasant and less stressful experience for all concerned.

If adequate time is taken to observe the dog' s initial reaction to walking in the front door of the veterinary hospital, many unpleasant situations may be able to be avoided. Observation of the cat in its carrier can also provide valuable information on how best to proceed. Understanding and appreciating that the way an animal behaves is influenced not only by its genetic makeup and inherited predisposition but also its previous experiences (and what it has learned from them) we can try to make veterinary visits more pleasant for all. If we also appreciate that the current environment will also affect the way an animal behaves at a given time it is easy to see that by adapting our approach to each individual animal and each specific situation it should be possible to modify the pets 's reactions and response (behavior).

WHAT IS AGGRESSION?

Aggression can be defined as a threat, challenge or attack that is directed towards one or more individuals. It can be intra-specific or inter-specific. Aggression may be normal or abnormal depending on the context in which it occurs.

All animals can be aggressive. Aggression can be a normal behavioral response to a perceived threat or challenge. When faced with a fear provoking stimulus the flight, fight, or freeze response may be evoked. Aggression is a nonspecific sign, that is, it may be exhibited in many different situations. It may be passive (covert) or active (overt) and it is important to recognise that several different "categories" of aggression may occur concurrently. Pain is a common trigger for aggression.

The signs that are presented may be:

- visual (eg, changes in body posture, piloerection),
- auditory (eg, growling, hissing, spitting),
- olfactory (eg, spraying, scratching,) or
- tactile (scratching) and may involve use of teeth, claws, head

WHY DO THEY EXHIBIT AGGRESSION AT THE VETERINARY HOSPITAL?

The first step in recognizing why a dog or cat may be aggressive at the veterinary hospital is to look at the hospital from the animal's perspective. Start by assessing the sights, sounds, and smells from the animal's perspective. Many of the sights, sounds, and smells of a veterinary hospital that we take for granted can and do have a profound effect on our patients.

Try to walk in their paws! All dogs can bite. Some need less provocation than others. The main reason that dogs are aggressive in the veterinary clinic is they are anxious or fearful. It is very unlikely that they are being dominant as many assume.

Anxiety has been defined as the apprehension of future danger. The dog's response to anxiety provoking situations will be to fight, freeze, flee or "fiddle." Which response it uses will depend to some degree on what it has found successful in controlling the situation previously. Thus, if the dog has previously learned that snapping at the perceived threat has lead to it having some control over the situation, it is much more likely to react this way again next time.

Many dogs have also been taught that growling is an unacceptable behavior. Thus, the full behavioral sequence beginning with the warning is altered or truncated and the dog may resort to snapping or biting without giving a warning.

Cats can also exhibit aggression in a veterinary hospital situation. They may bite and scratch and inflict damage on the staff in the process. The reasons for aggression in a veterinary hospital can be many including fear, anxiety, and pain.

SO WHAT MAKES ANIMALS ANXIOUS OR FEARFUL?

Some dogs and cats are genetically more fearful or apprehensive than others. This is an important consideration and is not necessarily related to breed but rather lines of dogs or cats and may be a trait of the individual.

The senses of dogs and cats are also very different from ours. A dog's hearing is about four times more acute than ours, and they can hear ultrasound and infrasound, as can cats. Thus, dogs and cats can become sensitized to the noises in a veterinary clinic and this can make them apprehensive or reactive and more difficult to handle.

A dog's sense of smell is at least 1,000 times better than ours (some dogs can detect fingerprints on glass 6 weeks after they were placed there!). Cats are probably not dissimilar. Veterinary clinics have very distinct odors that can be disturbing to dogs and cats despite having easily cleaned surfaces that are not porous. Dogs and cats can also detect the pheromones that can communicate alarm or distress.

Dogs and cats are predators and as such are very good at detecting very slight movements. They can be easily startled by movement. Thus, sudden movements can also increase their apprehension and so animals need to be approached slowly and calmly to help make them more tractable.

Consideration also needs to be given to the surfaces that they stand or lie on. Many animals find it frightening to walk or stand on slippery surfaces. A dog that is already apprehensive may become even more reactive unless surfaces with secure footing can be provided to decrease anxiety and reactivity.

In addition, some of the medications used in a veterinary clinic can increase reactivity. For example, acepromazine increases noise sensitivity and may lead to more unpredictable behavior.

PREVENTION

A well run Puppy Preschool® or Kitten Kindy® class conducted at the veterinary hospital can provide a good introduction to the veterinary hospital; the outcome is having well-mannered dogs and cats in the veterinary hospital. These classes, run by experienced staff, allow the puppy or kitten, as well as the owner, to become familiar with the veterinary hospital in a non-threatening manner and associate it as a "friendly" place to visit.

MINIMIZING PROBLEMS

If the pet is already apprehensive about coming to the veterinary hospital the aim should be to make each subsequent visit less difficult than the current one. The attitude of the staff and the hospital environment can do much to help things run smoothly.

At all times, however, please remember you should not put your safety or that of others at risk!

So what can we do to make life easier for the pet, the veterinarian, the staff, and the owner?

TIPS FOR HANDLING AGGRESSIVE DOGS AND CATS

- SAFETY FIRST
- Walk in their paws – think of the world from their perspective
- TAKE YOUR TIME!
- ***DO NOT PUNISH!*** Physically punishing aggressive animals may make the situation worse, especially with frightened or anxious dogs and cats.
- Train young puppies and kittens to enjoy wearing a head collar and muzzle
- Have muzzles, head collars, towels ready in advance
- Ask the owner to muzzle the dog prior to coming to the clinic
- Initially ignore the dog and talk to the owner
- Never make direct eye contact with the dog or cat
- Watch your body language
- Approach quietly, calmly and slowly
- Whisper and breathe slowly
- Approach from the side, not from front or behind
- Offer treats
- Speak softly, calmly
- Slowly stroke (not pat) on the chest
- Don't use physical force
- ***Never*** use force or aggressive behaviours to deal with aggression.
- Use minimal restraint
- Use anxiolytics if necessary
- Do not be afraid of anaesthetizing animals
- DAP / Feliway
- Pre-medication **prior** to putting in the cage
- Use signs on cages to warn others eg (I Bite)
- Keep records on what works AND what does not to make it easier for all next time.
- Remember than an animal's behaviour will change day to day eg if in pain or not
- Put aggressive dogs on ground level cages to make it easier to get them in and out.
- Insulate metal cages with eg pink batts to decrease noise
- Use non-slip matting on examination tables to provide secure footing and decrease anxiety
- **Don't be afraid to walk away for another day!**

KITTEN KINDY® AND PUPPY PRESCHOOL® – GOOD PRACTICE BUILDERS

Kersti Seksel, BVSc (Hons), MRCVS, MA (Hons),
FACVSc (Animal Behaviour), Diplomate ACVB, CMAVA
Sydney Animal Behaviour Service
Seaforth, New South Wales, Australia

Our future depends on having pets that fit into our society. Therefore, it is our duty to help the pets in our community fit in to the society in which they are to live. Kitten and puppy socialization and training classes benefit not only the kitten or puppy and the owner, but also the veterinary hospital and the community. How to run them successfully and how to avoid future problems are key aspects of these classes. Properly run classes conducted at the veterinary hospital by veterinary staff will help build a veterinary practice that is respected in the community.

BACKGROUND

"Behave" is defined in the Macquarie dictionary as "to act in a socially acceptable manner." Thus, the idea behind running kitten and puppy socialization and training classes is to help our pets become more socially acceptable to their owners as well as the community.

Behavior is influenced by three main factors. These are:

- An animal's genetically inherited tendencies or predisposition to exhibit a particular behavior
- The animal's previous experience and what it has learned
- The particular environment at the time, including the motivation at the time

It is also important to distinguish between "problem behaviors" and "behavior problems." When people talk about an animal's problem behaviour, it is when the pet does not behave as they wish, it is usually a normal behavior but socially unacceptable to the owners. However, some animals exhibit abnormal behaviors and these need to be identified and managed very differently.

PET OWNERSHIP

The reason that people decide to own a pet will influence how they perceive their pet. For example, if they see their pet as a companion rather than an "item" needed to indulge their sport or giving them prestige or security, the way they interact with the pet will vary.

Many studies have suggested that there are health benefits of owning pets, such as a reduction in stress, blood pressure, and serum triglyceride levels, but this is unlikely to be the reason for people deciding to own a pet.

Although there are many benefits of pet dog ownership, there are also known to be problems as evidenced by the number of dogs that are surrendered to pounds each year. This would seem to indicate that dogs exhibit behaviors which lead to a disruption of the human–companion animal bond. Each year about 20% of urban dogs are surrendered to pounds and animal shelters and of these, 80% are euthanized. Surveys indicated that up to 80% of these dogs were surrendered because of behavior problems.

The largest cause of death of pets is said to be euthanasia due to behavioral problems. Most dogs and cats do not live to their full age potential, with the average age of dogs estimated to be only 3.5 years while for cats it is 5.6 years.

There are many factors that appear to increase the risk of pets being euthanized or abandoned. Incorrect choice of pet, unrealistic expectations of the pet, and an undervaluing or perhaps, and ignorance of the time, money and effort required to be a *socially* responsible pet owner all contribute to the problem. The large numbers of dogs and cats surrendered worldwide is a tremendous financial and emotional burden to the people and organizations involved in dealing with the problem. Interventions that might reduce the likelihood of euthanasia or abandonment of pets, such as Puppy Preschool® and Kitten Kindy®, should help reduce these problems.

The reported prevalence of problem behaviors or behavior problems ranges from 42% to 87%. The most common problems, apart from aggression, that owners report to veterinarians and dog trainers include such behaviors as digging, jumping up, barking, destructiveness, and chewing. The most common problems in cats are elimination problems and aggression to other cats and to people. These all form part of an animal's normal behavioral repertoire. Although many feel it is important to "stop" these behaviors It is possibly detrimental to the animal's welfare to try to stop them entirely. That is not to say, however, that they cannot be modified to a more socially acceptable behavior by altering the time, place, or duration of the behavior.

To be successful in trying to change the occurrence of these behaviours, it is essential that the owner understands why the pet may be behaving in this way and how to respond accordingly. A little basic understanding of the nature of dogs and cats and their needs can be very helpful in dealing with the problem. *This is one of the important reasons for running Puppy Preschool® and Kitten Kindy® classes.*

In general, confinement and lack of activity may often exacerbate some of these unacceptable, destructive and nuisance behaviors. Dogs and cats are highly intelligent, active, social animals that need activity, company and stimulation (both physical and mental!).

Counselling owners about the most suitable pet for their particular circumstances BEFORE they actually acquire a pet would be the ideal situation. This is a service that many of us can offer but few do so at present. Offering advice on choosing a pet based not only on owner lifestyle, owner expectations and personal preferences as well as their dog's innate characteristics may help owners deal better with the behavior and make their expectations of the dog or cat more realistic.

WHAT IS SOCIALIZATION?

Socialization is defined as a special learning process where an animal learns to accept the close proximity of members of its own species as well as that of other species. Therefore, animals that are well socialized will be able to live in harmony with others.

WHAT ARE PUPPY SOCIALIZATION AND TRAINING CLASSES (PUPPY PRESCHOOL®)?

Puppy Preschool® is specifically designed for puppies 8 to 14 weeks of age to help them become sociable and manageable pets. They are NOT obedience classes for younger dogs.

Puppy Preschool® aims to help prevent behavior problems, educate owners on all aspects of raising a puppy and then living with a dog in the family, as well as establish a close bond between the puppy, the owner, and the veterinary hospital if that is where they are conducted. Training puppies has to be fun as well as appropriate, not only for the puppy but also for the whole family.

Why Do We Need Puppy Preschool®?

Being a puppy is one of the most important stages in a dog's life. This is the vital age to start training and socialising the puppy as everything the puppy sees and experiences will have a great effect on how he behaves as an adult.

As is well recognized, puppies have a sensitive period of development called the socialization period that occurs from about 3 weeks to 3 months of age and any experiences the puppy has during this time can affect later behavior. From many early studies it is now known that dogs that have been isolated during this time are more likely to be hyperactive, aggressive, difficult to train, antisocial, and fearful.

To develop into normal, friendly and confident adults, puppies need to be regularly handled and to be exposed to many new and novel situations in a non-threatening way. Puppies that are not exposed to other dogs during the socialization period are more likely to develop aggressive or fearful responses to other dogs later, just as puppies that are not socialised to humans often develop behavioral problems. Unfortunately many puppies are not homed until after this age or go to homes where they may not experience a wide variety of situations.

They also need to interact with dogs of various breeds if they are to be well-behaved members of our community. Starting puppies off the right paw is much easier (ie, teaching the puppy the correct and socially acceptable behavior) than trying to correct bad behaviors later, when the puppy has had 6 months or more to learn them. Puppy Preschools® are a safe way of helping a puppy to be well socialized and start with the basics of training.

Dog owners also need to be educated and taught how to look after and to train their pets to become suitable members of the community. Most dogs are kept as companion animals and it is for this reason that puppy training classes are an essential part of teaching owners how to teach their puppies basic good manners rather than traditional obedience type exercises.

KITTEN SOCIALIZATION AND TRAINING: KITTEN KINDY®

Although the advantages of puppy training are now well established and accepted, many people still do not appreciate that kittens would also benefit from such classes that focus on early handling and training. Cats require socialization with members of their own species as well as humans and dogs if they are to become social members of the household. Studies have shown that early handling of kittens in a gentle, non-threatening manner is just as important for cats as dogs for their normal development.

Kitten Kindy® is an early socialization, training, and education program designed to help owners and kittens start off on the right track together. The goal of Kitten Kindy® is to help prevent behavioral problems, educate owners on all aspects of raising a kitten, and then live with a cat in the family. They aim to establish a close bond between the cat, the owner and the veterinary practice.

Kitten Kindies® are ideal for kittens under 12 weeks of age to help them develop into manageable and social adult cats. Because of the socialization period of cats kittens should be no more than 14 weeks old when they finish the classes. Kittens more than 14 weeks old may be more likely to fight rather than socialize with the other kittens. The classes allow kittens to explore new environments, learn to play with other kittens, play with toys and develop confidence in new surroundings. Ideally, the younger the kitten the better for maximal socialization. Hand-raised kittens or kittens from small litters appear to benefit especially from these social interactions.

The classes should also aim to teach owners about normal feline behavior as well as how to play and interact appropriately with their kittens. The focus should also be on teaching owners on how to prevent problems behaviors as well as on other preventative medicine issues.

PLANNING CLASSES

For maximum benefit the classes should be are held at your Veterinary Hospital. This way the pets and their owners meet you and your staff and become familiar with the hospital. However, these classes need careful planning. The outcome of the classes should be considered in advance. This should include the aims and outcomes.

The classes need to be fun, as well as providing a relaxed and safe environment for learning both pets and owners. They should be run by the *most* experienced trainers that are familiar with learning theory and canine/feline behavior.

The classes should aim:

- To educate owners on *socially* responsible pet ownership
- To inform owners about normal canine/feline

behavior
- To explain to owners how to train their puppy/kitten at home
- To allow puppies/kittens to socialize in a safe and controlled situation
- To teach puppies/kittens to accept gentle handling from humans
- To teach puppies/kittens manners
- To teach puppies/kittens to be calm on cue
- To provide solutions to common issues such as housetraining, biting, scratching, jumping, chewing
- To encourage ongoing training for dogs
- To help owners to have realistic expectations of their pets
- To build a strong bond with the practice

Benefits
- Better behaved adult pets
- Better educated owners
- Better educated veterinary staff
- Increased self esteem for staff
- Increased practice profits
- Increased client visits

Behavior is controlled by its consequences. If the consequence is "good" then the behavior is likely to be repeated, and conversely, if the consequence is "bad" the behavior is unlikely to be repeated. This is one of the key concepts that needs to be understood when dealing with animals.

LEARNING THEORY

The two principles of learning that are commonly used when discussing how to modify the behavior of dogs and cats are classical and operant conditioning. Classical conditioning, also known as Pavlovian conditioning, was first studied by Pavlov in the early part of the last century. Conditioning is said to have occurred when the repeated pairing of a neutral stimulus (Conditioned Stimulus, CS) with a biologically significant event (an unconditioned stimulus, UCS), results in the production of a response (Conditioned response, CR) when the CS is presented alone For example, the words "good dog" are initially neutral—that is, these words mean nothing to the dog. However, they may become a CS via Pavlovian conditioning by being paired with biologically significant events such as presentation of a food treat or a pat on the head. The conditioned response in this example is likely to be tail wagging.

Operant conditioning, or instrumental learning, is the primary method in which dog training is achieved. Operant conditioning teaches the animal to perform a voluntary response in order to obtain a reward. Presentation of a positive reinforcement or reward, such as food, increases the chances of a particular response being repeated Hence, the dog learns that behavior is controlled by its consequences. Similarly, an animal will perform a behavior to obtain secondary rewards, or stimuli, consistently presented with the primary reinforcer (for example, for the words "good dog" which were paired with food presentation).

The likelihood of a particular behavior being repeated depends on the nature of the consequences. Thus, if the consequence is pleasurable, such as a piece of food or a game, then the behavior is more likely to be repeated. Using this methodology new behaviors can be shaped in the animals. For example, behaviors such as "sit" or "stay" can be taught to be expressed in response to a verbal and, or visual cue.

DEFINITIONS

Reinforcement - Increases the chances that behavior will recur.

Positive Reinforcement - This is a reward (something pleasurable) that, when given immediately after a response, **increases** the probability of that same behavioral response occurring again. For example, if a dog is rewarded for sitting by being given a tasty piece of food after being given the cue "sit," then the dog is more likely to sit next time that same verbal cue is given.

To be most effective the reward has to be:

- Immediate
- Consistent
- Desirable

Negative Reinforcement - This is often confused with punishment. It is something unpleasant or aversive that, when it is removed immediately after a response, **increases** the probability of that response recurring. For example, loosening the choke chain after a dog stops pulling on it teaches the dog that it is less painful to walk to heel than to pull on the lead.

Punishment - Decreases the chances of the behaviour recurring.

Positive Punishment - It **decreases** the probability of the preceding response occurring again. Positive punishment is the addition of an aversive stimulus or event. For example, yelling at the dog or smacking would be considered a punishment if it lead to a decrease in the behavior.

To be most effective the reprimand needs to be

- Immediate
- Consistent
- Sufficiently aversive

Negative Punishment - The withdrawal of a pleasant stimulus or event that leads to a decrease in a behavior is considered a negative punishment. For example, placing a dog into a "sin bin" immediately after performing an unacceptable behavior would be considered a negative punishment if it leads to a decrease in that behavior.

Timing - The timing is crucial with both reinforcement and punishment. The time between the response and the punishment or reinforcement must be immediate, less than 1/2 second for the animal to make an association. By reinforcing 5 seconds after the response the learning time, ie the time for the animal to make an association may double.

In summary, reinforcement increases the probability of a response; punishment decreases the probability of response.

MODIFYING BEHAVIOUR

Training essentially means teaching animals what we want them to learn. Most training involves the use of operant conditioning. It is very effective as there is "something in it" for the animal. However, classical conditioning is also very important and often overlooked.

Learning is fastest when the reward is given immediately after the desired response (preferably within ½ second), very desirable and given every time the response occurs.

A continuous reinforcement schedule (when rewards are given every time a response is made) is used to teach a response, but does not help maintain the response. When the rewards cease, often so does the behavior.

A better way to ensure continued performance is to use what is called a variable reinforcement ratio. This may mean rewarding at set intervals, perhaps every third or fourth response. However, it is important not to introduce this until the desired response is learned. Once a response is learned it will become very difficult to extinguish if the rewards are then given intermittently. The poker machine (slot machine) is a great example of its effectiveness in people.

Punishment is the least effective way of changing a behavior, yet it is the technique that generally animals (and people) experience the most. Just think about how often the word "no" is said to the average dog in its lifetime? And think about how often it is effective.

Punishment is not reliable when trying to modifying behavior because it does not teach what behavior is actually expected in the circumstances—that is, it does not lead to an alternative response.

In addition, despite what the name may infer punishment does not have to be **painful** and it does not necessarily mean physical punishment. Punishment may also impede learning as it may increase anxiety. Repeated use of punishment decreases its effectiveness. Think about how often you have said, "If I've told you once, I've told you a thousand times not to ...." Generally, a good rule of thumb is if the same punishment has to be administered more than three times it means that the principles are not being followed and it is unlikely going to be effective.

In practice it is very difficult to effectively administer punishment and it is easier and more useful to teach the desired response instead.

MODIFICATION OF BEHAVIOR IN PRACTICE

When animals exhibit unacceptable behaviors, there are many issues that need to be considered when trying to change these behaviors.

- A behavior modification program is likely to be more successful if the following are addressed.
- The client understands the underlying cause(s) of the behavior.
- The client understands the basic principles of learning theory.
- The client understands the pet's motivation to perform the behaviors.
- The client has realistic expectations—no pet will ever be perfect even if it appears that their last pet was!
- Some behaviors are not changeable or modifiable.
- Behavior modification takes time and patience. It is not an overnight quick fix so setting realistic time frames in which to expect changes should be addressed.
- The client recognizes that they will have to maintain the behavior modification program for the life of the pet.
- The client appreciates that a consistent approach is needed.
- To be effective any behavior management program needs the full commitment of not only the owner, but also the owner's family. Everyone who is in regular contact with the pet needs to be consistent in their interactions with the pet. If someone cannot or will not follow the protocols it is better that they ignore the animal instead of interacting with the animal.
- Regular recheck appointments and follow-up phone calls are scheduled.
- The training is realistic with regard to time commitment and level of complexity.
- The training is fun for both client and pet.

Factors that may decrease the likelihood of success include:

- The client has unrealistic expectations of the pet. Not all dogs can or will be Lassie!
- The client has unrealistic expectations of what can be achieved and in what time frame.
- The client is unaware that as a behavior management program is instigated the pet may actually get worse before it gets better. As the owners start to alter the way they interact with the pet it may take some time for the pet to adjust to the new routine.
- Unanticipated or even unexpected responses occur. These need to be worked through step by step with the owner and possible reasons explained.
- The program is too involved or complicated, too time consuming or too difficult.
- There is disagreement between the owners as to what the problem actually is, the severity of the problem, etc.
- The motivation to persist with the behavior modification program decreases over time so that the problem behaviors reappear.
- The client feels that no ongoing support is available.

Points to Remember

- Animals go on learning whether we intend to teach them to or not.
- They learn by watching us.
- They learn by watching conspecifics.
- They learn fastest when they are rewarded every time.
- They learn fastest when the reward is very desirable.
- We can shape an animal's behavior by repeatedly rewarding behaviors that successively become closer to the one we want.
- A behavior can become extinct if it is ignored (not rewarded).
- Behaviors that have been intermittently rewarded take the longest to become extinct.

Ten Top Tips

- As behavior is determined by its consequences make each consequence good
- Reward acceptable behaviors, ignore unacceptable behaviors
- Reward immediately
- Use desirable rewards
- Reward intermittently once the behavior is learned
- Be patient
- Avoid punishment
- Teach good manners
- Motivation is important
- Have fun!

HEAD COLLARS – DIFFERENT TYPES, HOW THEY WORK AND HOW TO FIT THEM

Kersti Seksel, BVSc (Hons), MRCVS, MA (Hons)
FACVSc (Animal Behaviour), Dipl. ACVB, CMAVA
Sydney Animal Behaviour Service
Seaforth, New South Wales, Australia

WHAT ARE HEAD COLLARS?

Head collars are a training tool. They are a piece of equipment that fits on the dog's head much like a halter fits on a horse or cow. There are many designs and brands available for dogs.

The general principle of all head collars is a strap that fits around the dog's neck and another strap that sits across the dog's nose (muzzle). In most cases the lead attaches under the dog's chin and there may be a "connector" that acts as a safety device that attaches to the dog's regular collar. There are some head collars where the lead attaches at the back of the dog's neck.

WHY USE HEAD COLLARS?

Head collars are used to help teach dogs to walk on a loose lead (ie, without pulling). They are useful to help the dog focus on the owner and break the dog's attention on other dogs or people. They are commonly recommended for many behavior problems. They can also be used to help during a veterinary examination. They appear to have a calming effect on some dogs.

WHICH IS THE BEST HEAD COLLAR AND HOW TO CHOOSE ONE?

The best head collar is the one that fits the dog the best. The choice of head collar will depend on the shape of the dog's head and the length of the dog's nose. Color, style, and owner preference also play a part in deciding which head collar is used. The previous experience of the head collar fitter with various types will also affect choice.

Some dogs appear to more easily accept collars where the leash attaches behind the neck better while other dogs better accept head collars where the leash that attaches under the chin.

TEACHING DOGS TO ACCEPT A HEAD COLLAR

All head collars should be fitted properly by someone who knows how to do so. This may take up to 20 minutes to achieve. The neck strap should fit high and tight on the neck. It should be snug (like a watch strap fits on the wrist). The nose loop should be tight enough so that the dog cannot get it off but loose enough so that the dog can still open its mouth and pant. If pulled towards the nares it should not be able to be pulled over the nose.

It is a good idea to let the dog get used to the pressure of head collar before the leash is attached. A very light leash (such as a cat leash) should be the first one used to accustom the dog to the added pressure. It may take several weeks for some dogs to accept wearing a head collar.

It is important for the dog to get used to accepting the light pressure of the nose loop on the muzzle in stages. Start by rewarding the dog, with small pieces of tasty treats, when it sits. Then reward when the dog puts its nose near the nose loop. Then encourage the dog to put its nose through the nose loop. Always reward immediately.

The more the dog practises putting its nose through the nose loop before moving to tightening the neck strap the better.

Once the dog seems happy putting its nose through the nose loop, slowly increase the time the nose loop rests on the dog's nose. Over time, with rewards, the dog should look forward to putting its nose through the nose loop.

Only then start doing up the neck piece. Give the dog treats at each step. When the dog accepts wearing the head collar it is a good idea to let the dog wear it for variable periods of time around the home. Eating with the head collar will let the dog associate the head collar with positive experience. The head collar should not be taken off at any stage if the dog scratches or paws at it (unless the dog is really distressed). If the dog fusses at the head collar the dog should be distracted and asked to sit and focus on the owner. It should be rewarded when it does. Only once the dog is relaxed should the head collar be removed.

THE DOG ACCEPTS THE HEAD COLLAR – WHAT NEXT?

Attach the lead and practice at home. If the dog pulls then the owner should stop moving. When the lead is loose then can the owner move forward again. If the lead tightens then the owner should stop moving forward and start again only when the lead loosens.

THE DOG IS NOT HAPPY WITH THE HEAD COLLAR – WHAT NEXT?

The major problems are:

- Insufficient time to get used to the head collar
- Neck strap not snug enough
- Inaccurate fitting of head collar
- Incorrect choice of size/ type of head collar
- Taking head collar off when the dog is fussing

Loosening the neck strap means that the head collar is more uncomfortable for the dog as it will rotate more.

DIFFERENT TYPES OF HEAD COLLAR

There are several types of head collar available; some of these are shown in Figure 1. Each collar fits slightly differently. Consult the relevant Web site for each collar for detailed step by step instructions on their use.

MUZZLE TRAINING

Kersti Seksel, BVSc (Hons), MRCVS, MA (Hons),
FACVSc (Animal Behaviour), Diplomate ACVB, CMAVA
Sydney Animal Behaviour Service
Seaforth, New South Wales, Australia

MUZZLES

Muzzles are one of the tools veterinary staff can use to minimize the chances of injury when examining aggressive or reactive dogs.

Ideally muzzles should be introduced to dogs when there is no need for them. This can be done in a Puppy Preschool® class or at the puppy's first visit. It can also be done by owners of the more reactive dogs at home to help keep veterinary office staff safe.

There are several types of muzzle commercially available. Custom made muzzles are also available for dogs. This is especially useful for brachycephalic breeds and those dogs with broad or large muzzles.

Regardless of the type of muzzle, it should not cause distress to the dog; it should allow the dog to pant and the owner to give treats for relaxed or appropriate behavior. A basket-style muzzle (either plastic or leather) is usually the best choice as it allows dogs to pant and drink water if needed. Therefore, they can be used for extended periods as well as when the dog is exercising.

Many dogs that are anxious bite. A common sign of anxiety is panting, so in order to decrease or at least not increase the dog's anxiety the muzzle should allow the dog to pant comfortably. For this reason, basket-type muzzles tend to be the best option for dogs that are anxious, exercising, or wearing the muzzle for any time periods more than a few minutes. Even in the short term, the ability to pant means that stressed dogs are less anxious.

WHY USE MUZZLES

Apart from being important for the safety of staff when examining reactive dogs, there are many reasons to use muzzles. Muzzles help owners of aggressive dogs to relax and also act as a warning to approaching dogs and people that the dog is reactive. This can be very useful for reactive and aggressive dogs.

Muzzles will reduce the risk of bite injuries. However, they are not an absolute guarantee in this regard as muzzles can break or come off and dogs can still do damage by bowling other individuals over and causing bruising.

FITTING A MUZZLE

If the dog is introduced to the muzzle gradually, then most dogs will accept it very readily. It is important to first encourage the dog to approach the muzzle and offer a treat. Once the dog readily approaches the muzzle then it is possible proceed to the next step. Fitting a muzzle may take a considerable period of time and requires patience.

Start by placing a tasty piece of food on the strap end of the muzzle and allow the dog to eat it. Over a few repetitions it will be possible to place food treats further into the muzzle itself so that the dog puts its muzzle further into the basket. It takes time for a dog to get used to having his muzzle in an enclosed space so do not proceed too quickly. Smearing sticky food such as peanut butter into the bottom of the muzzle will increase the length of time the dog spends with its nose in the enclosed area of the muzzle. Only when the dog is relaxed should there be any attempt to do up the neck strap, even momentarily.

As the dog accepts putting his nose into the muzzle slowly progress to having the dog wear the muzzle for more than a few seconds. If the dog is relaxed and does not attempt to remove the muzzle or fuss at it then proceed to keeping the muzzle on the dog for progressively longer periods, say a minute, then two, and so on.

The dog should always have a positive association with wearing the muzzle. Pairing wearing the muzzle with good things, such as walks, meals, or attention will help the dog accept the muzzle more quickly. Indeed many dogs actually look forward to wearing the muzzle at it brings rewards.

Some muzzles will need a little modification to allow food treats to be given easily. Treats such as vegemite, peanut butter, pâté, and cream cheese can all be applied to the end of the muzzle as an added incentive to want to keep it on, too.

Even when the dog is comfortable wearing the muzzle, it is important for the dog to be rewarded periodically with food when the dog is wearing it so that the dog continues to associate the muzzle with pleasant experiences.

DIAGNOSIS AND TREATMENT OF PERICARDIAL EFFUSION

Matthew W. Beal, DVM Diplomate ACVECC
College of Veterinary Medicine
Michigan State University, East Lansing, MI

Pericardial effusion is defined as the accumulation of fluid within the pericardial space. As the pressure within the pericardial space increases, right-sided cardiac filling is impaired, resulting in decreased stroke volume with subsequent decreases in cardiac output and ultimately decreased oxygen delivery to the tissues (shock). These manifestations of pericardial effusion are referred to as cardiac tamponade.

TRIAGE AND PHYSICAL EXAMINATION

The most common presenting complaints from the owners of dogs with pericardial effusion and cardiac tamponade are lethargy, anorexia, collapse or syncope, abdominal distention, and dyspnea. Vomiting also appears to be a somewhat common complaint additionally. Major body systems assessment of the dog with pericardial effusion will likely reveal compromise to one or all of the major body systems (cardiovascular, respiratory, and CNS).

Upon identification of compromise to the major body systems, the patient should be moved to the treatment area for further assessment including full physical examination, measurement of blood pressure, oxygen saturation, cardiac rhythm (ECG), and placement of an intravenous catheter from which a small blood sample for packed cell volume (PCV), total solids (TS), blood glucose +/- venous blood gas and electrolytes + lactate can be rapidly acquired. If possible, blood for complete blood count (CBC), serum biochemical profile, and coagulation profile or activated clotting time (ACT) should also be collected. Concurrently, a second team member will be able to collect a full medical history.

Physical examination should still be centered on the major body systems, but subtle findings supportive of pericardial effusion may be noted including:

- Jugular venous distention +/- jugular pulses: due to right sided congestive heart failure.
- Muffled heart sounds/normal lung sounds
- Abdominal distention: ascites and hepatic engorgement may result from longstanding (days) pericardial effusion/cardiac tamponade due to right-sided congestive heart failure. Abdominocentesis will frequently reveal a relatively clear fluid will low cellularity and a protein concentration greater than 2.5 g/dL but less than 3.5 g/dL most consistent with a modified transudate.
- Pulsus paradoxus: An inspiratory fall of arterial systolic blood pressure of more than 10 mmHg resulting in variation in pulse intensity with respiratory cycle due to increased venous return during inspiration, increased right-sided filling, shifting of the interventricular septum to the left with decreased left-sided diastolic filling and subsequent decreased left-sided stroke volume. Pericardial effusion causing cardiac tamponade should be HIGHLY suspected based on signalment, history, and physical examination findings, supported by diagnostic testing such as abdominocentesis and electrocardiography (+/- radiography) and confirmed through point of care diagnostic imaging techniques (echocardiography).

DIAGNOSTIC TECHNIQUES

Electrocardiography

Assessment of ECG in patients with pericardial effusion may reveal sinus tachycardia +/- ventricular arrhythmias. Ventricular arrhythmias may result from decreased myocardial oxygen delivery or aberrant conduction associated with the underlying cause of the effusion. QRS complexes <1 mV in amplitude and the presence of electrical alternans (regular or irregular variation in QRS complex amplitude associated with the heart moving within the pericardium to and from the positive pole of lead II) are supportive of pericardial effusion.

Echocardiography

Echocardiography is the diagnostic test of choice for rapid, stress-free confirmation of the presence of pericardial effusion in the dog. Many dogs with pericardial effusion have SEVERE cardiovascular compromise and can be on the verge of death. The stresses associated with radiographic imaging may put cause these patients to decompensate. Echocardiographically, pericardial effusion appears as a hypoechoic space located between the hyperechoic pericardium and the right ventricular wall when viewed through the right cardiac notch (Figure 1). The presence of pericardial effusion provides excellent contrast to aid in the diagnosis of cardiac masses; however, pericardiocentesis should NOT be delayed in a patient with signs of shock simply to aid the diagnosis.

Thoracic Radiography

As previously mentioned, thoracic radiography can be an extremely stressful procedure for dogs with cardiac tamponade. However, not all practices are equipped with ultrasound capabilities. If thoracic radiography is performed in dogs with suspected pericardial effusion, ventrodorsal positioning should be avoided in favor of dorsoventral positioning. Lateral thoracic radiographs may also be performed. Supportive radiographic findings include an enlarged, globoid cardiac silhouette. Acute effusions may not cause severe enlargement of the cardiac silhouette because the pericardium has not had time to enlarge. Concurrent pleural effusion may be present. The other primary differential for a globoid heart is dilated cardiomyopathy (DCM) or other underlying cardiac disease. Key findings to try to differentiate DCM from pericardial effusion include:

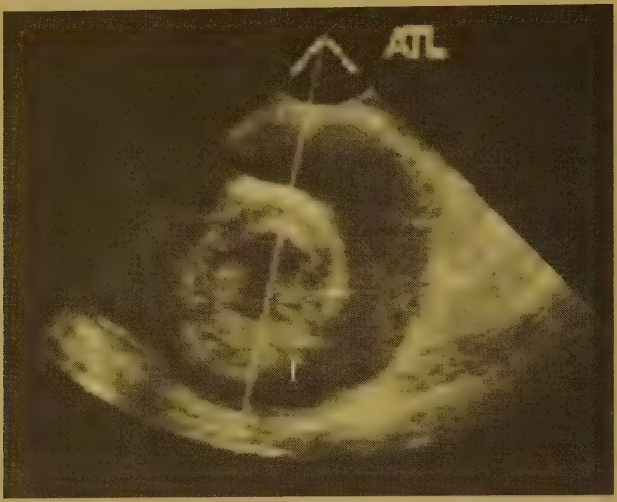

Figure 1. Echocardiogram from a dog with pericardial effusion. Note the hypoechoic fluid (f) surrounding the left ventricle (v).

- **Heart sounds:** Heart sounds in dogs with DCM are frequently normal in contrast to the decreased heart sounds seen in pericardial effusion. A systolic murmur may be noted in dogs with DCM and is uncommon in dogs with pericardial effusion.
- **ECG:** Atrial fibrillation is common in dogs with DCM. Atrial fibrillation is uncommon in dogs with pericardial effusion. Electrical alternans may be seen in dogs with pericardial effusion.
- **Cardiac Silhouette:** The silhouette of the heart on thoracic radiographs of dogs with pericardial effusion tends to be extremely round with sharp borders. The silhouette of the heart in dogs with cardiomyopathy can be round, but often, there are still some dimples or "waist" associated with the divisions between the chambers and the borders of the cardiac silhouette tend not to be as sharp because of motion artifact.
- **Pulmonary infiltrate:** Pulmonary edema is common in DCM and uncommon in pericardial effusion.
- **Pulsus paradoxus:** Common in pericardial effusion, uncommon in DCM.

ETIOLOGY

Pericardial fluid accumulation and cardiac tamponade in the dog most often occurs secondary to a neoplastic process. Hemangiosarcoma (HSA) is most commonly identified in the region of the right atrium or right atrial appendage while chemodectoma (common in brachycephalic breeds) is most often identified at the heart base. Mesothelioma and any metastatic tumor are additional neoplastic causes. Although location and breed are frequently suggestive of tumor type, definitive diagnosis is dependent on a biopsy specimen.

Idiopathic pericardial effusion tends to be an inflammatory process and is frequently recognized in similar breeds to those that develop HSA. Significant efforts in recent years have been directed towards developing diagnostic tests to help differentiate malignant from benign pericardial effusion (idiopathic). Pericardial fluid pH was initially thought to aid in making this differentiation; however, pericardial fluid pH has now been clearly shown to be of little diagnostic value. Evidence suggests that blood concentrations of cardiac troponin I (cTnI) are significantly higher in dogs with masses consistent with HSA than in dogs without evidence of an underlying cause (idiopathic).

Vitamin K_1 antagonists (anticoagulant rodenticides and coumadin) can also result in pericardial effusion. Therefore, it is the author's practice to always perform an ACT or other point-of-care coagulation assessment prior to pericardiocentesis. If significant coagulopathy is present and patient condition permits, correction of coagulopathy with blood products (fresh frozen plasma or fresh whole blood) is indicated prior to pericardiocentesis. Subsequent institution of Vitamin K_1 therapy for 4 weeks is indicated.

Left atrial tear is an uncommon consequence of chronic mitral regurgitation and left atrial dilatation; however, it has been recognized as a cause of acute pericardial effusion in the dog.

An infectious cause of pericardial effusion is fungal disease (coccidiomycosis). Bacterial pericarditis and pericardial effusion secondary to trauma also occur, but are uncommon.

Numerous additional conditions such as congestive heart failure, uremia, decreased oncotic pressure, and a host of systemic inflammatory processes frequently result in small volume pericardial effusion accumulations without evidence of cardiac tamponade.

PERICARDIOCENTESIS

Pericardiocentesis can be a stressful procedure. Use of cardiovascularly sparing sedatives (opioids and benzodiazepines) may alleviate patient stress and facilitate safe pericardiocentesis. Numerous techniques have been described for pericardiocentesis in the dog including, but not limited to the use of a large-gauge over-the-needle catheter, through-the-needle catheter, and catheters placed using the Seldinger technique. The author prefers to use a 14- to 16-gauge, 5.5-inch over-the-needle catheter with two additional small side-holes or a commercial 6F multi fenestrated locking loop pigtail catheter (Infiniti Medical, New York, NY) placed using the Seldinger technique. The latter may be left in place for ongoing drainage.

The ECG should be monitored during and after pericardiocentesis for the presence of arrhythmias induced by catheter-associated irritation of the epicardium and decreased myocardial oxygen delivery experienced during cardiac tamponade. Lidocaine should be readily available, as should a defibrillator.

Pericardiocentesis is most often performed from the right hemithorax because injury to the left coronary artery is unlikely, and the cardiac notch is slightly larger. The patient can be positioned in sternal recumbency (preferred by most) or laterally. Full surgical preparation should be performed between the 2nd to the 8th ribs and from the mid-thorax to the level of the sternum. A fenestrated drape should be placed. Aseptic technique should be practiced at all times. The apex beat of the heart should be palpated (most often between the 4th and 5th ribs just above the costochondral junction) and lidocaine should be infiltrated locally off the cranial edge of the rib (to avoid the intercostal neurovascular bundle). Ultrasound guidance can also be used to identify the optimal location for pericardiocentesis. A small skin incision (<5 mm) should be made in the proposed insertion site and the catheter advanced through this incision (off the cranial edge of the rib). Upon the appearance of fluid in the flash chamber, the catheter and stylet should advance together for 2 to 3 mm and the catheter fed over the stylet into the pericardium. Initially, a small fluid sample should be placed in an ACT or clot tube. A sample retrieved from the ventricle should clot (unless the underlying condition is anticoagulant rodenticide intoxication) while one that has been in the pericardial space for any appreciable period of time should not. A fluid sample should be saved for cytologic analysis and culture and the pericardium should be evacuated.

MONITORING

Patient response to decompression of significant pericardial effusion is often very rapid and very gratifying as vital signs and physical examination findings improve dramatically. Monitoring for recurrence of fluid accumulation by frequent reassessment of major body systems, physical examination and echocardiography is useful.

PROGNOSIS

Prognosis for dogs with pericardial effusion will depend on the underlying cause of the disease. Surgical removal of a mass on the right atrial appendage will alleviate signs of acutely recurrent pericardial effusion. Surgical removal of right atrium/appendage hemangiosarcoma followed by chemotherapy will prolong life in dogs with pericardial effusion.[9] Pericardectomy will temporarily palliate clinical signs of pericardial effusion for most neoplastic processes, and will most often be curative for idiopathic pericardial effusion. Thoracoscopic pericardectomy or creation of a pericardial window may have similar effects.[10-11] Balloon pericardiotomy is currently under investigation as an alternative palliative procedure. Treatment with fresh frozen plasma, vitamin K1, and pericardiocentesis will be curative for dogs with anticoagulant rodenticide intoxication. Culture and sensitivity based antimicrobial therapy +/- surgical debridement is indicated for the management of infectious pericarditis. Dogs with left atrial tear secondary to chronic mitral valve regurgitation and left atrial dilation carry a guarded prognosis. Surgical repair of such a lesion has been described.[13]

HYPERTENSION – TARGET ORGAN DAMAGE AND THERAPY

Anthony P. Carr, Dr. med. vet., Diplomate ACVIM
Western College of Veterinary Medicine
University of Saskatchewan, Saskatoon, Canada

WHAT IS HYPERTENSION?

Hypertension is a sustained elevation of blood pressure that is higher than "normal" for that patient. As routine measurements are not done in all clinics, we cannot always refer to the individual's normal blood pressure but have to compare it to either breed-specific values or according to normal ranges established by the Veterinary Blood Pressure Society and ACVIM Hypertension Consensus Group. Rather than speak of mild, moderate, or severe hypertension it is better to refer to the risk of end organ/target organ damage (TOD). Hypertension is not only a symptom of a disease but also a disease in itself as it causes damage, mainly to the eyes, the heart, the kidney and the brain.

Risk Categories	Systolic Pressure	Diastolic Pressure
I	<150	<95
II	150–159	95-99
III	160–179	100-119
IV	≥180	≥120

It is important to judge systolic and diastolic pressure individually as we can differentiate between:

- Isolated systolic hypertension: only systolic blood pressure is high, diastolic is normal
- Isolated diastolic hypertension: only diastolic blood pressure is high, systolic is normal
- Mixed hypertension: both systolic and diastolic blood pressure are elevated

Each type of hypertension occurs in dogs and cats and each type can cause TOD.

WHAT TYPE OF HYPERTENSION CAN BE FOUND IN DOGS AND CATS?

Dogs and cats, unlike human beings, suffer predominantly from secondary hypertension. That means that there is an underlying disease causing blood pressure to rise. In some individuals it is not yet possible to diagnose an underlying problem; these cases are referred to as "idiopathic hypertension." The ACVIM Hypertension Group recently published a consensus statement on blood pressure that establishes this terminology (J Vet Intern Med. 2007;21(3):542-558).

HOW DOES HYPERTENSION DEVELOP?

In most instances, hypertension develops because of increased vascular constriction, in some diseases such as hyperthyroidism increased cardiac output may also be a contributing factor. One of the main regulating systems responsible for hypertension via vasoconstriction is the renin-angiotensin-aldosterone system (RAAS), which is also activated in heart and renal insufficiency. Increased adrenergic tone or responsiveness to catecholamines may play a role in some diseases as well. In rare instances, blood viscosity can increase leading to hypertension. This can be the case with gammopathies (ehrlichiosis, multiple myeloma) or polycythemia. Depending on the underlying disease additional mechanisms can contribute to hypertension.

TARGET ORGAN DAMAGE AND THERAPY

The Heart as a Target Organ

High blood pressure means elevated preload but more importantly elevated afterload for the heart. Consequently the heart has to react to pressure load and compensate for the additional work. The increased wall tension is sensed by mechanoreceptors which then initiate the processes by which a variety of signals such as release of growth factors, intermediate peptides (eg, endothelin and angiotensin II) and alpha-adrenergic stimulation leads to changes in the myocardium. Both myocardial hypertrophy and myocardial hyperplasia occur. The result of both is more or less marked wall thickening (concentric left ventricular hypertrophy) and increase in heart muscle mass. By increasing wall thickness, wall stress is reduced (relationship of LaPlace); however, left ventricular compliance is reduced (decreased diastolic function). This hypertrophied cardiac muscle is more sensitive to adrenergic stimulation and ischemic injury. Growth factors together with tissue hypoxia stimulate collagen synthesis. Reduced diastolic function can result secondary to the chronic cardiac changes. RAAS activation may further induce increased arteriolar tone and increased coronary vascular resistance, in cats hypertrophy of the coronary arterioles has been reported (Littmann MP: Spontaneous systemic hypertension in 24 cats. J Vet Intern Med. 1994; 8(2):79-86)

Clinical Findings:

- **Auscultation:** Abnormal auscultatory findings are frequent in dogs and cats (70% of feline hypertensive patients in: Elliot et al, J Small Anim Pract. 2001;42;122-129). Cardiac murmurs are not infrequently encountered. This may also be partially caused by concurrent issues such as anemia from chronic renal failure or hyperthyroidism. Gallop rhythms are common because of decreased ventricular compliance. Arrhythmias can also occur, though they are more common when other diseases are present that predispose to them such as hyperthyroidism.
- **ECG:** Findings are not specific for hypertension. Common findings are tall R waves (high voltage), increased heart rate and less frequently taller P-waves and dysrhythmias.
- **Thoracic Radiographs:** Mainly left sided cardiomegaly, enlargement and tortuosity of the aorta
- **Echocardiography:** Left ventricular enlargement often with asymmetric or symmetric thickening of the

intraventricular septum and the left ventricular free wall. Mitral insufficiency is often detectable. Unlike with hypertrophic cardiomyopathy left ventricular diameters in diastole tend to be preserved.

The Kidney

In an animal with impaired kidney function, hypertension provokes a more rapid progression of the kidney disease, as it damages the nephrons and can contribute to proteinuria. This is especially true in patients with renal disease as they have lost autoregulation, in other words the ability of the kidney to control renal blood flow and GFR. This sets up a vicious cycle where kidney disease increases blood pressure which then increases loss of renal function. Renal failure undoubtedly is the leading cause of hypertension in small animal practice. With loss of autoregulation there is also a concomitant inability to maintain renal perfusion when hypotension occurs. This is especially important in patients with renal disease that are anesthetized. Hypertension (even with normal renal function) generally leads to a decreased ability to compensate for hypotension, renal failure can occur.

The Eyes

The eyes are commonly affected by hypertension and as a result retinal examination of all animals with suspected hypertension is recommended. Given that hypertension is most common in older patients including a retinal exam as part of the general physical exam in older cats should be considered. Blood supply to the retina is via the choroid and the retinal arteries. Retinal arteries have autoregulatory capability, as blood pressure increases they vasoconstrict. This is not true of the choroidal vessels. With prolonged hypertension this can lead to areas of ischemia with eventual rupture and hemorrhage (hypertensive retinopathy). With hypertensive choroidpathy, severe bullous retinal detachments are more common. A hypertensive optic neuropathy can also be encountered.

Clinical Findings. A variety of clinical signs can be seen. Hyphema can occur; often this results initially in uveitis;, with persistence, secondary glaucoma can result. Unilateral or bilateral mydriasis with poor to absent PLRs may be seen as may be blindness. Examination of the posterior segment will reveal retinal vascular tortuousity, hemorrhage and detachments. Older lesions may be present that reveal retinal degeneration and retinal hyperreflectivity. There are other diseases that can cause similar lesions such as vasculitis, hyperviscosity, bleeding disorders, etc.

The Brain

Although hypertension can cause damage to the brain it is important to remember that brain disease can lead to systemic hypertension as well via the Cushing reflex. If intracranial pressure increases there is a concomitant increased in systemic blood pressure to help maintain blood flow to the brain. The brain is another organ that possesses the ability to autoregulate blood pressure and blood flow to the brain. With hypertension, cerebral vessels are constricted to prevent the hypertension from being passed down to smaller arteries which would be more susceptible to injury and therefore potentially begin to hemorrhage. Persistent hypertension leads to chronic changes to blood vessels with hypertrophy. This can lead to areas of ischemia or hemorrhage. Hemorrhage into the brain is irritating resulting in inflammation (meningitis, myelitis, encephalitis). In the brain, hypertension can also result in edema which can further exacerbate dysfunction.

Clinical Findings. Clinical signs are relatively variable and can include behavior changes, depression, seizures, salivation, cranial nerve abnormalities, and potentially coma.

TREATMENT

Which Drugs Should be Considered?

- ACE Inhibitors, to:
  - Lower blood pressure (in general 10 to 20 mmHg) by reducing pre- and afterload
  - Will also have an anti-proteinuric effect that may be advantageous in some cases with renal disease
  - Will preferentially dilate the postglomerular (efferent) capillary, resulting in a decrease in intraglomerular pressure as well as GFR (usually only mild decrease in GFR resulting in mild increases in azotemia) even if the drop in blood pressure is modest. Though renal values may rise, this treatment will slow progression of renal disease by acting renoprotective.
- Dihydropyridin Calcium Channel Blockers (eg, amlodipine), to:
  - More aggressively lower blood pressure
  - Good efficacy and safety has been documented in cats
  - Preferentially dilate the preglomerular (afferent) capillary. This will maintain GFR, however if blood pressure reduction is not adequate, intraglomerular pressure can rise resulting in further loss of renal function.
- ß-blockers to:
  - Contribute to regression of left ventricular hypertrophy
  - Reduce heart rate
  - Especially if hyperthyroidism is concurrently diagnosed with cardiac changes
  - Efficacy unproven in veterinary medicine
- Diuretics, to
  - Further support diuresis, thus lowering pre- and afterload
  - Primary choice in humans, efficacy doubtful in small animal patients.

In summary, treatment should depend on the underlying disease, but adequate decrease of hypertension must be obtained.

BLOOD PRESSURE MEASUREMENT: COMPARISON OF TECHNIQUES

Beate Egner, Dr.med.vet.
Clinical Center for Small Animals
Mainhausen - Hoerstein, Germany

Blood pressure measurement becomes more and more of a routine procedure in veterinary practice. Although it is not a difficult task per se, there are some requirements which need to be followed to allow fast and reliable readings. However the most important prerequisite is **the willingness to measure blood pressure!**

Many authors described the influence of environmental stress but also the influence of an impatient examiner on blood pressure. Thus certain requirements have to be fullfilled to allow a relaxed and fast reading and reliable results:

- Blood pressure measurements should be taken in a quiet room
- Visitors or employees should not walk in and out of the room while a patient is measured
- The animal should have a few minutes to get used to the environment and the overall situation
- The animal should be handled in a calm and patient manner
- The pet's owner should be present provided he or she is able to calm the animal
- In each clinic, one or more individuals should be responsible for appointed to obtain blood pressure measurements to ensure consistent technique
- Measurements should be taken in a relaxed position
- The appropriate equipment should be used and limitations (Doppler, conventional oscillometry, plethysmography) should be well known to allow a correct interpretation of the results
- When using HDO technology, measurement is easiest on the base of the tail, but can also be obtained on the limbs

Allow the animal to adjust to the environment:

- Cats: Take the cat out of its kennel. Let the cat decide on the preferred position and whether to sit on the examination table or being held in the arm of the pet owner.
- Small dogs: The patient can be placed on the examination table or held by the owner
- Large dogs: If possible, take the measurements with the patient positioned on the floor

Positioning of the patient:

- It is most important that the measurement site is at about the level of the base of the heart.
- That can be ensured when measuring the patient in
    - "Down" position at the base of the tail or on the front limb below the elbow
    - Lateral recumbancy, with the cuff being placed on the base of the tail or that front limb, which is on the ground
    - Standing position, measuring on the base of the tail

BLOOD PRESSURE MEASUREMENT TECHNOLOGY

In general, since both the systolic and diastolic blood pressure are important to analyze, technology should be used that can measure both values.

Currently the most reliable of these technologies is HDO® (High Defintion Oscillometry), which just recently has been patented. It is a totally new technology with an algorithm developed specifically for animals. Due to its high-speed processor (32-bit compared with 8-bit of conventional oscillometric and invasive/direct units), it is the first technology allowing visible real-time measurements. Furthermore, HDO additionally offers GAIN, which magnifies very small amplitudes allowing measurements in a patient with shock or with arrhythmias. Another new feature of this technology is the individual adaption of deflation rate according to the pulse rate, allowing rapid blood pressure determination in animals with high heart rates, for example, cats.

With HDO a graphical display of the oscillations recorded by the blood pressure device is possible. Analysis of the graphs provides additional information regarding cardiac output and vascular status.

HOW TO INTERPRET THE GRAPHS?

An HDO screen shot of a normal and regular rhythm, with constant cardiac output, is shown in Figure 1. Technical features of the different blood pressure measurement systems—Doppler, conventional oscillometry, and HDO—are listed in Table 1. Implications of the different technologies for practical applications are summarized in Table 2.

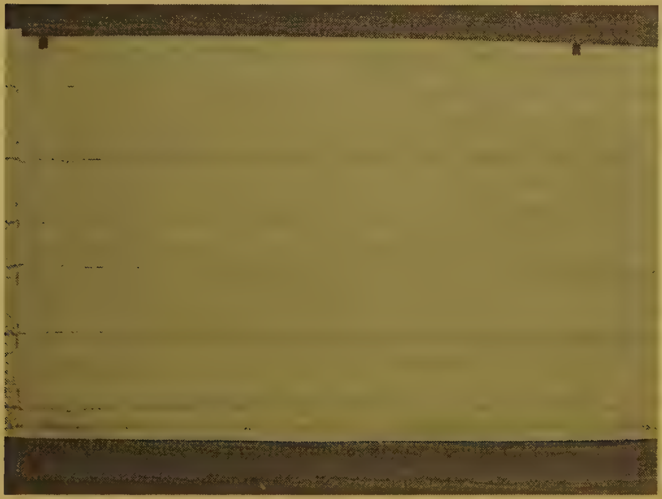
Figure 1. An HDO screen shot of a normal and regular rhythm, with constant cardiac output, is shown in Figure 1. Systolic and diastolic pressures are indicated as red- colored amplitudes. All parameters set can be viewed in the right window "Function Parameters."



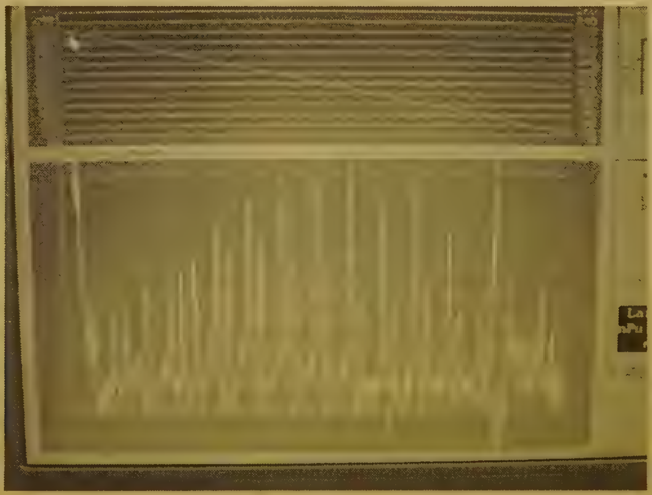


Figure 2. This in contrast is a patient with sinus block as it can be seen on the corresponding ECG. Different amplitudes indicate different cardiac output situation (prolonged diastolic filling during the block, thus higher CO after the block), block can also be seen on HDO as pauses.

Figure 3. The picture of, for example, premature beats can be very similar, so an ECG is still needed to characterize the arrhythmia found on the HDO-screen.

Table 1. Technical Features of the Different Blood Pressure Measurement Systems*

	Doppler	**Conventional Oscillometry**	**High-definition Oscillometry (HDO)**
Gain	Acoustic detection of the return of blood flow (dependent on the examiner's individual hearing capacity and reaction speed at which the examiner can visually observe and mentally register the numbers on the sphygmomanometer gauge)	Fixed preset values for recognition of pulse waveforms and amplitudes	Allows automatic or manual adjustment of amplitude recognition settings (amplification) for each individual patient (range: 70 to 640 X)
Artifact recognition	Not possible	Two approximation strategies are used (depending on manufacturer) • Fuzzy logic • Feedback loop	Recognized artifacts are eliminated and do not interfere with measurements
Valve action	Mechanical valve; Linearity from ~160–80 mmHg	Mainly mechanical valves; sometimes electronic valve Linearity from ~160–80 mmHg	Electronic valve Can be programmed towards a linearity of 0-300 mmHg
Pulse-dependent linear deflation rate / cutoff value	Valve-determined cutoff value at approx. 160 mmHg; Since the mechanical valve is opened manually, linear deflation of cuff is not possible	Valve-determined cutoff value at approx. 160 mmHg; Valve is opened automatically (mechanical or electronic valves, the sensitivity of which can be adjusted more or less variably); Real-time analysis and, hence, real-time valve programming is not possible (8-bit processor);	Valve-determined cutoff value at approx. 160 mmHg; Real-time analysis and real-time valve programming is possible in the 0–300 mmHg pressure range (32-bit processor)
Processor speed and sampling rate	Real-time analysis not possible; Dependent on the examiner's hearing and reaction capacity; Detailed analysis not possible	Real-time analysis not possible; Permits pulse rate-dependent analysis (160–250 max., depending on the system), on average, of one entire amplitude in a maximum measurement range of 0–250 mmHg	Permits real-time analysis; Provides much higher resolution and permits analysis within micro-seconds; can therefore detect even the smallest signals and measure extremely high heart rates of 400 beats/min and higher

SILDENAFIL – WHAT YOU NEED TO KNOW

Amara Estrada, DVM, Diplomate ACVIM (Cardiology)
College of Veterinary Medicine
University of Florida, Gainesville, FL

Pulmonary hypertension (PHT) is a life-threatening disease that is uncommonly diagnosed in canine patients. It is defined as an increase in pulmonary arterial pressures greater than 25 mmHg in systole and 15 mmHg in diastole. PHT is typically diagnosed in patients noninvasively via transthoracic echocardiographic estimations of pulmonary arterial pressure. There are numerous published etiologies for PHT traditionally divided into (1) primary or idiopathic PHT and (2) PHT secondary to an underlying disorder. Diseases that are commonly seen to result in secondary PHT include chronic respiratory disease (chronic bronchitis, interstitial lung disease, high altitude exposure), pulmonary thromboembolism, diseases causing increased left atrial or left ventricular end diastolic pressures (degenerative mitral valve disease, cardiomyopathies, congenital heart disease) or diseases directly affecting the pulmonary vasculature (heartworm disease). Most dogs with mild to moderate PHT are asymptomatic and thus are likely undiagnosed. Dogs with more severe PHT may present for exercise intolerance, syncope, lethargy or potentially signs of right-sided congestive heart failure. Treatment goals in patients with PHT include attempts to identify and treat any underlying etiology as well as management of signs of right-sided congestive heart failure should they exist. Effective management of primary/idiopathic PHT has historically been limited as most vasodilators exert a fourfold higher effect on the systemic vasculature than on the pulmonary circulation thus causing systemic hypotension long before any appreciable decrease in pulmonary pressures occur.

In the pulmonary vasculature, cyclic GMP (cGMP) allows for pulmonary vasodilation. Phosphodiesterase-5 (PDE-5) is an enzyme located primarily in the bronchi and trachea which is responsible for the breakdown of cGMP. An agent that selectively blocks PDE-5 should therefore increase cGMP levels in the pulmonary vasculature and cause pulmonary vasodilation with little effect on the systemic vasculature. Sildenafil (Viagra®) is a PDE-5 which has been used in humans and is now being used in veterinary patients for the treatment of primary PHT. Numerous, small, single-center case reports and case series have been published on the use of sildenafil in humans, and now in veterinary patients as well. Results from these studies indicate that there is improvement in clinical status, both in the short and long term, in patients treated with sildenafil for PHT caused by many etiologies.

Sildenafil is expensive, but certainly more tenable for veterinary medicine than other agents (such as prostacyclin analogues and endothelin receptor antagonists) routinely used in the management of PHT in humans. Sildenafil is currently the most extensively researched of the PDE-5 inhibitors, and has been shown to improve both exercise tolerance and quality of life in humans with PHT resulting in its FDA approval for the treatment of PHT.

Sildenafil is available in multiple tablet sizes but the cost per tablet is the same regardless of drug concentration (Pfizer, $9.90 per tablet regardless of size. Available tablet sizes include 100 mg, 50 mg, and 25 mg). Multiple dosages ranging from 20 mg to 80 mg three times a day have been used in humans with PHT. No increase in the efficacy was seen at the higher dosages and the currently recommended dose in humans is 50 mg every 8 hours. In order to minimize costs, at the author's institution, we purchase the 100 mg tablet and either quarter or halve this tablet, or have it reformulated to fit our patient's needs.

Stability of a reconstituted sildenafil liquid formulation has been reported. We typically start a patient at 1–2 mg/kg twice a day and try to up-titrate to a dosage of 2–3 mg/kg three times daily (over several weeks). In response to the effectiveness of treating PHT with Viagra®, Pfizer has now re-released sildenafil as Revatio® (Pfizer, $9.70 per 20 mg tablet). This formulation is quite expensive and is not used by the author. In conclusion, sildenafil has markedly improved our ability to reduce clinical signs and improve quality of life in patients with PHT. Sildenafil is routinely used at the author's institution in combination with other cardiac medications for the management of PHT and heart failure including pimobendan, digoxin, low-molecular-weight heparins, aspirin, ACE inhibitors, and furosemide.

PIMOBENDAN AND HEART DISEASE – BREAKING UPDATE

Amara Estrada, DVM, Diplomate ACVIM (Cardiology)
College of Veterinary Medicine
University of Florida, Gainesville, FL

The majority of positive inotropic agents used today in the United States increase contractility by increasing cytosolic calcium. Increased intracellular calcium not only increases myocardial oxygen consumption, but can also lead to the development of dangerous arrhythmias. Phosphodiesterase III inhibitors, such as milrinone, were initially available as oral medications for chronic inotropic support, but were withdrawn from the market because of observed increased risk of sudden death in patients treated long term. Phosphodiesterase III inhibitors are still available and approved for intravenous acute inotropic support but the package insert gives a prominent warning regarding safety when given for longer than 48 hours.

Calcium sensitizing drugs were developed to function differently than conventional inotropic agents such as digoxin, milrinone, or dobutamine. Rather than causing an increase in cellular calcium, these agents were to sensitize the contractile apparatus to the existing level of calcium within the cell. Theoretically, these agents should increase contractile force without causing increase in cellular calcium and thus alleviate the concern of calcium-induced arrhythmias with use. This expectation has not been met in the case of several members of this group, including levosimendan and pimobendan, which also have phosphodiesterase inhibitory properties in addition to the calcium sensitizing properties.

Pimobendan (Vetmedin®) is a relatively new drug licensed for use in Canada and Europe for the treatment of congestive heart failure secondary to chronic mitral valvular insufficiency in dogs. Pimobendan is an orally active drug combining calcium sensitizing properties with cyclic AMP phosphodiesterase III inhibition. As such, it has both positive inotropic effects and peripheral vasodilatory effects, thus it is also called an "inodilator." The Food and Drug Administration has recently announced the approval of Vetmedin in the United States for the management of congestive heart failure in dogs due to chronic mitral valvular insufficiency or dilated cardiomyopathy. Chewable tablets were scheduled to be released and available for sale in September 2007.

Because of its phosphodiesterase activity, much concern has been raised regarding arrhythmogenesis with use of pimobendan. Drug trials in normal dogs treated with pimobendan did not find an increase in the incidence of arrhythmias. One veterinary clinical study evaluating use of pimobendan did find an increase in the number and severity of ventricular arrhythmias. This was a small study, in which half of the dogs enrolled were Doberman Pinschers with dilated cardiomyopathy (DCM), a disease frequently associated with malignant ventricular arrhythmias which progress naturally. This increase in arrhythmias may have just as likely been due to disease progression. Another clinical study in veterinary medicine found no increase in the frequency of ventricular arrhythmias following pimobendan therapy in dogs with degenerative mitral valve disease. Anecdotal evidence and clinical experience with pimobendan do not suggest any increase in dangerous arrhythmias with use; however, more studies and clinical experience with the drug are still needed to assess this aspect.

As an "inodilator," pimobendan incorporates properties that are very desirable in the clinical management of *systolic congestive heart failure* secondary to both DCM and chronic degenerative mitral valve disease (MVD) in dogs. Significant improvement in long-term survival and reduced severity of clinical signs has been shown in dogs with congestive heart failure due to DCM or MVD treated with pimobendan. Review of available data suggests that pimobendan appears to be safe and well tolerated when used in combination with conventional therapy (ACE inhibitors, digoxin, diuretics) in these patient groups.

While there appears to be ample evidence of the beneficial effects of pimobendan for patients with systolic congestive heart failure, there is not currently a consensus regarding use in patients with asymptomatic (pre-congestive) heart disease. Additionally, there is evidence that treatment with a positive inotropic agent such as pimobendan prior to the development of systolic myocardial failure can have deleterious effects. Experimental data have shown that valvular and parietal endocardial jet lesions could be induced within 4 weeks in healthy dogs even in the absence of previous valvular disease. In addition, clinical reports of dogs chronically treated with pimobendan have described adverse cardiac effects, such as increased regurgitant fraction and left atrial enlargement, which were in part reversed following cessation of pimobendan therapy. Moreover, a recent prospective study in dogs with naturally occurring mild, asymptomatic mitral valve disease treated with pimobendan demonstrated increased regurgitant fraction and induction of mitral valve lesions including acute focal hemorrhages, endothelial papillary hyperplasia, and infiltration of chordae tendinea with glycosaminoglycans. These reports raise an important issue: is pimobendan indicated in dogs without systolic myocardial dysfunction? While the answer is not entirely clear at this point in time, careful case selection when deciding when and how to use pimobendan is advised and at present, it should be reserved for use when systolic myocardial failure is detected or suspected.

LOW-MOLECULAR-WEIGHT HEPARINS — HOW TO USE THEM

Amara Estrada, DVM, Diplomate ACVIM (Cardiology)
College of Veterinary Medicine
University of Florida, Gainesville, FL

Low-molecular-weight heparins (LMWHs) are an alternative to unfractionated heparin (UH) in the treatment of cats with, or with the potential for, thromboembolic disease. Although UH has been used for decades, our understanding of all of the pharmacological actions of this substance in animal patients is still incomplete. Recently, much work has been done on fractionating heparin into lower-molecular-weight forms since they appear to have advantages over UH in humans including a significant reduction in therapy-induced hemorrhagic complications and a more predictable anticoagulant effect without the need for traditional laboratory monitoring required by UH.

Important pharmacological differences exist between LMWH and UH. As a result, LMWH can selectively inhibit Factor-Xa to reduce the likelihood of thrombus formation, while minimally affecting clotting times. LMWHs play an important role in prophylaxis and therapy of humans with thromboembolic disease. LMWHs in human clinical trials have been proven safe and effective in preventing and treating venous, arterial, and intracardiac thromboembolism. Similarly, LMWHs have been discovered in both dogs and horses to be safe and well tolerated, with minimal side effects and no bleeding complications. LMWHs have also been shown in humans, dogs, and horses to have a minimal effect on the common coagulation tests (eg, thrombin time, activated partial thromboplastin time [APTT]) that are often used to monitor conventional heparin therapy.

In the cat, however, much less is known about LMWH administration. The proper dose, dosing interval, method of monitoring, side effects, and effectiveness of the different LMWH agents are still unspecified. Most current recommendations have been either speculated from studies in other species or are anecdotal from prior experience. This is unfortunate because aortic thromboembolism secondary to cardiomyopathy is a fairly common and serious disease of cats.

In attempts to identify a safe, easily administered, effective anticoagulant medication in cats, several small veterinary studies looking at LMWH in cats have been conducted. One pharmacokinetic study in 8 healthy cats suggested that therapeutic concentrations of anti-FXa (as defined in humans) were achieved with a 100 IU/kg once daily dose of dalteparin given subcutaneously. A dose of 200 IU/kg of dalteparin was also adequate, however, it caused a significant prolongation of the APTT. No clinical signs of bleeding or other problems related to drug administration were observed during this study. Another similar study using dalteparin in 8 normal cats at a dose of 100 IU/kg subcutaneously twice daily was used. The data from this study suggested that this dose of dalteparin was inadequate to achieve an anticoagulant effect. Other laboratory values, such as prothrombin time (PT), APTT, antithrombin III (AT III), platelet count, and packed cell volume, were not significantly affected by the LMWH. A third study evaluating enoxaparin (1 mg/kg) and dalteparin (100 IU/kg) at twice daily dosing suggested that while adequate effect (evaluated via anti-FXa values) was achieved 4 hours post LMWH administration, this effect was gone by 8 hours. Conclusions from this study were that cats receiving LMWH therapy needed more frequent dosing than twice a day in order to be effective. Lastly, an ongoing study being performed at our institution using enoxaparin (2 mg/kg) and dalteparin (200 mg/kg) administered twice daily had a variable effect on normal cats with some having profound elevations in anti-FXa levels and others having no increase above baseline. In cats with the highest levels of anti-Xa activity, elevated APTT values and increased bleeding and bruising following venipuncture were noted.

In conclusion, we have learned a lot regarding use of LMWH in cats but there is much we still do not know. We know that in normal cats, there appears to be tremendous variation in individual response to dosage. Dosages of 1 mg/kg enoxaparin and 100 IU/kg dalteparin, every 12 hours, subcutaneously, appears to be safe, and will be effective in achieving the human target anti-FXa activity levels in the majority, but not all, of cats treated. However, we do not know what anti-FXa activity level conveys protection from thrombosis and thromboembolism in normal cats, and know even less about this in cats with cardiomyopathy. Ideally, anti-FXa activity should be measured after 48 hours of use, to ensure any particular cat is not resistant to the drug. Increases in dosage (above 1 mg/kg enoxaparin and 100 IU/kg dalteparin, q 12 hours) should be initiated only when monitoring of anti-FXa levels is performed. The cost and availability of such testing, in addition to the expense of LMWHs, may potentially make this approach in veterinary medicine impractical.

TREATING FELINE HEART FAILURE

Philip R. Fox, DVM
Diplomate ACVIM/ECVIM (Cardiology) & ACVECC
The Animal Medical Center, New York, NY

Cardioimyopathy—disease of the heart muscle—is responsible for more than 95% of feline heart disease. The most common cause of symptomatic heart disease is diastolic heart. Many affected cats remain asymptomatic for life, although the incidence is uncertain.

DIASTOLIC DYSFUNCTION

Diastolic dysfunction results from a wide range of heart muscle disorders that promote ventricular stiffness and loss of compliance via diverse mechanisms that alter loading conditions; increase myocardial mass (hypertrophy); cause myocardial injury (inflammation, myocytolysis, necrosis), repair (fibrosis, matrix changes), myocyte disorganization, or ischemia. Arrhythmias, heart failure, or thrombovascular complications can develop.

WHAT IS DIASTOLIC HEART FAILURE?

These changes can lead to increases in left ventricular filling pressure and mean left atrial pressure. The term *diastolic heart failure* refers to the development of pulmonary edema in cases of abnormal diastolic function in the setting of relatively normal contractility (systolic performance).

GOAL FOR MANAGING FELINE HEART DISEASE

The primary goal for managing heart disease is to improve survival by reducing morbidity and mortality. Most treatment strategies await validation.

MANAGEMENT OF THE ASYMPTOMATIC CAT

Ideally, treatment should prevent disease progression, reduce risk factors, or decrease morbidity and mortality. Presently, there is little data to guide whether therapies should be implemented throughout the lifetime, or indicate when or which treatment should be initiated. Nevertheless, certain circumstances appear to increase risk of cardiovascular morbidity and therefore merit consideration for therapy.

POTENTIAL CARDIOVASCULAR RISK FACTORS

Substantial abnormalities involving myocardial structure or function appear to promote adverse outcome, thereby providing the raison d'être for pharmacologic intervention. The following may warrant therapy, although efficacy remains to be proven.

Myocardial Infarction

Myocardial infarction may be inferred by echocardiography. Rationale for angiotensin-converting enzyme inhibitor (ACEI) therapy is based upon the potential of these agents to favorably influence ventricular remodeling and reduce mortality in people and in experimental animals. The rationale for beta-adrenergic blockers similarly includes reduction of infarct size, myocardial oxygen utilization, and reduced mortality.

Tachyarrhythmia

Rapid tachyarrhythmias can reduce cardiac filling, promote ischemia, and cause hemodynamic instability. Sustained tachyarrhythmias are usually associated with myocardial disease with attendant cardiac remodeling (myocyte necrosis, fibrosis, inflammation, and interstitial matrix changes). It is prudent to consider antiarrhythmic therapy in selected cases, particularly when the ventricular rate is rapid.

Massive Left Ventricular Hypertrophy (Severe Hypertrophic Cardiomyopathy [HCM])

Cats with greatly increased left ventricular mass (maximal diastolic septal or left ventricular wall thickness > 8 mm) may be at increased risk for cardiovascular events.

Syncope

Recurrent syncope is a risk factor for sudden death in humans with HCM, and retrospective feline studies have related syncope and poor outcome. Syncope can be associated with tachyarrhythmias, dynamic left ventricular (LV) outflow obstruction, and ischemia. Symptoms can often be managed successfully with beta-blockers to reduce or abolish LV outflow tract obstruction.

Spontaneous Echo Contrast ("Smoke")

Spontaneous echo contrast is associated with blood stasis. This finding is considered to presage thrombosis, is associated with increased thromboembolic risk, and should therefore warrant antiplatelet drugs (aspirin) and perhaps more aggressive therapies.

"Malignant" Familial History of Sudden Death (High-Risk Genotype)

Pedigrees may be identified with a documented heritable pattern of HCM with severe morbidity and mortality (eg, Maine coon cats). Early intervention with calcium channel blockers or beta-adrenergic blockers may be contemplated based on experimental considerations, which hold that a pathway to the phenotypic expression of LV hypertrophy is influenced by triggers such as higher LV pressure and work load.

Myocardial Failure

In some HCM cats LV remodeling from infarction or other causes results in reduced contractility (eg, fractional shortening typically 22% to 29%) and/or increases LV end-systolic dimension (>12 mm). Therapies include oral taurine supplementation, ACE inhibitors to counteract neurohormonal activation and reduce remodeling, and judicious beta-blocker therapy if myocardial infarction is suspected, or if tachyarrhythmia is encountered.

Arrhythmic Right Ventricular Cardiomyopathy

Cats with advanced structural lesions (eg, severe right ventricle (RV) dilation, ventricular tachycardia) may be at risk for congestive heart failure (CHF). ACEI and potentially, antiarrhythmics (sotalol) should be considered in such cases.

MANAGING DIASTOLIC HEART FAILURE

Acute CHF (Pulmonary Edema)

Pulmonary edema is rapidly progressive and life threatening. Diuretics represent the cornerstone for acute emergency management. Furosemide administered intravenously causes peak diuresis within 20 to 30 minutes; inhibits renal sodium tubular reabsorption or its accompanying anions; promotes brisk diuresis; and reduces vascular volume decreasing LV filling pressures (ie, cardiac preload) and pulmonary congestion. Initial dosage is 1 to 2 mg/kg IV every 30 to 60 minutes until dyspnea associated with congestion is reduced. Then, dosage frequency is reduced, typically to every 8 to 12 hours. Alternatively, after one or more IV boluses, furosemide is administered via constant rate infusion (ie, based upon estimated dose for 24 hours). Resolution of pulmonary edema may be enhanced by application of transdermal 2% nitroglycerin ointment, ¼ to ½ inch every 6 hours. To reduce nitrate tolerance, alternate 12 hours with and 12 hours without nitroglycerine therapy. Supplemental oxygen (40% to 60% O_2-enriched inspired gas) may improve pulmonary gas exchange. Clinical improvement and resolution of congestion is indicated by reduced respiratory rate and work of breathing, resolved lung crackles, and radiographic clearing of alveolar infiltrates (usually by 24 to 36 hours). Dehydration, azotemia, and hypokalemia can result from over-diuresis.

Chronic Maintenance Therapies

Chronic therapy is individualized to maintain a congestion-free state; prevent arterial thromboembolism; halt, slow, or reverse myocardial dysfunction (theoretically); promote enhanced quality of life; and prolong survival. Treatable and contributory diseases should be identified and managed (eg, systemic hypertension, hyperthyroidism, and anemia). Therapy for each case must be individualized.

Ideally, treatment should be guided by clinical evidence that one or more drugs are safe and effective. The foundation of evidence-based medicine is randomized clinical trials designed to evaluate effects of specific therapies on morbidity and mortality. To help assess scientific data with an evidence-based perspective, one widely held technique qualifies clinical data according to four categories of evidence type (eg, Type A evidence results from large, prospective, randomized, controlled clinical trials designed to assess treatment and outcome; type D evidence is anecdotal or personal experience).

Chronic therapies consider administering one or more agents that include a diuretic, ACEI, beta-blocker, or calcium channel blocker. Furosemide is gradually decreased to the lowest effective dosage, typically, 6.25 to 12.5 mg every 12 to 24 hours). Some cats remain stable on 1 to 2 mg/kg PO given every other day while in others, diuretics may be used twice weekly or even discontinued. Preliminary data (Fox PR, for the Multicenter Feline Chronic Heart Failure Study Group. Prospective, double-blinded, multicenter evaluation of chronic therapies for feline diastolic heart failure: Interim analysis. J Vet Intern Med. 2003;17:398) from cats recovering from first onset of diastolic heart failure, and treated with either once daily administration of atenolol, dilacor, enalapril, or placebo (with background furosemide (6.25–12.5 mg/day), suggested that survival was shorter in the beta-blocker group. There was no statistical difference in survival between cats who received placebo versus diltiazem (Dilacor®). Cats in the enalapril group did as well or better than the placebo group.

Recurrent Heart Failure

Upward diuretic titration may be necessary with recurrent CHF. Diuretic resistance may occur as heart failure progresses, and cats with recurrent CHF are likely to benefit acutely from intravenous furosemide which has higher bioavailability. Addition of a second diuretic (eg, thiazide 5 to 10 mg daily, or spironolactone 12.5 to 25 mg daily) is reserved for cases of diuretic resistance. It is prudent to assess BUN, creatinine, electrolytes, and blood pressure in anorectic cats. Addition of other drugs is contingent on individual needs and underlying disease. Appropriate tests should be performed as needed to assess for systemic and metabolic disease (anemia, hyperthyroidism), cardiac structure and function (echocardiography), and other relevant conditions.

Thromboembolism

Antiplatlet aggregating therapy is considered when severe left atrial enlargement is present, when spontaneous echo contrast is evident in the LA or LV, or when cats have had previous thromboembolic episodes. Aspirin may be used, dosed at approximately 81 mg PO every three days, although lower doses have been suggested. Other agents are presently under investigation such as clopidogrel (Plavix®), 18.75 mg PO every 24 hours. Low-molecular-weight heparin drugs are added when cats have thromboembolic complications. Fragmin® (100 U/kg every 12–24 hours SQ) or enoxaparine (1mg/kg every 12 hours SQ) have been used relatively safely for chronic management, (optimal efficacy may require higher frequency of administration for Fragmin or higher doses, but every 6 to 8 hour administration rates may be impractical for long-term administration). Because hyperkalemia can follow re-perfusion injury, continuous ECG monitoring is valuable during the first 3 days following thrombosis. Periodic evaluation of BUN and electrolytes are useful.

ACUTE & CHRONIC CANINE HEART FAILURE: THE ROLE OF PIMOBENDAN

Sonya G Gordon, BSc, DVM, DVSc
Diplomate ACVIM (Cardiology),
College of Veterinary Medicine and Biomedical Science
Texas A&M University, College Station TX

Pimobendan has been licensed for use in dogs with heart failure since 2000 in many countries around the world, including Europe, Great Britain, Australia, Canada, and Mexico. Pimobendan is produced and marketed by Boehringer Ingelheim under the trade name Vetmedin®. Pimobendan was recently approved in the US for the treatment of canine heart failure due to dilated cardiomyopathy (DCM) and chronic degenerative valve disease (CVD).

Pimobendan is a novel agent with properties that are desirable in the management of the **clinical stage** of both DCM and CVD in dogs. **Preclinical heart disease** is defined as the stage of disease when a patient has evidence of cardiovascular disease but **currently and previously has no clinical signs** that can be attributed to their underlying cardiovascular disease—eg, clinically normal dogs with heart murmurs characteristic of CVD and or evidence of radiographic or echocardiographic left atrial enlargement who historically and currently have no clinical signs of cardiovascular disease. **Clinical heart disease** is defined as the stage of cardiac disease when a patient **has or had clinical signs** attributable to their cardiovascular disease—eg, cough due to cardiogenic pulmonary edema and or left atrial enlargement causing left main stem bronchial compression either at the time of the current exam or previously. Thus dogs with clinical disease may not have current clinical signs of cardiac disease if they are stable on cardiac medication. With perhaps the exception of a dog that was in heart failure due to a patent ductus arteriosus that was subsequently repaired dogs cannot go backward from the clinical stage of heart disease they can only become stable and free of clinical signs with appropriate therapy. The development of clinical signs attributable to underlying heart disease identifies the development of heart failure (HF). Independent of underlying etiology and species HF is defined as the inability of the heart to deliver adequate quantities of blood to meet metabolic tissue demands with normal filling pressures. Heart failure can be clinically classified as backward or congestive HF and or forward HF. Backward HF refers to the build up of fluid (congestion) and patients with backward HF can be considered 'WET.' Backward HF can be subdivided into right, left or biventricular backward HF. Clinical presentations suggestive of left sided congestive HF are those commensurate with cardiogenic pulmonary edema. Clinical signs suggestive of right sided congestive HF are those commensurate with ascites +/- pleural effusion. Forward HF refers to poor peripheral perfusion and patients with forward HF can be considered 'COLD.' Clinical presentations suggestive of forward HF are those commensurate with poor peripheral perfusion such as weakness, exercise intolerance or collapse.

THERAPEUTIC APPROACH TO HEART FAILURE

Some therapies for HF are independent of underlying etiology (nonspecific) and some target the abnormalities associated with the underlying etiology. For example, any patient with dyspnea due to severe cardiogenic pulmonary edema will benefit from, rest, oxygen and furosemide but only patients with ventricular systolic dysfunction would be expected to benefit from a drug that enhances the strength of ventricular contraction, such as pimobendan. In addition, consideration must be given to potential side effects and drug–drug interactions as well as client (cost and ease of administration) and patient (suspension, tablet, chewable) preferences.

We predominantly manage patients with clinical signs of backward HF. Isolated forward HF is rare however, patients with clinical signs of backward HF are at risk for the development of forward HF and thus management of backward HF should include therapies targeting preservation of perfusion. In general HF therapies aim to relieve/reduce clinical signs of backward HF, improve or prevent clinical signs of forward HF and prolong survival. Some medications work in more than one category enhancing their potential utility. For example pimobendan reduces preload and afterload through balanced arteriovenous dilation, improves ventricular systolic function, may help palliate clinical signs attributed to pulmonary artery hypertension and has salutary effects on maladaptive cytokine profiles in HF. Table 1 offers a summary of cardiovascular medications used in the management of DCM and CVD broken down by clinical stage: Clinical Stage (HF) versus Preclinical. Stage

THERAPEUTIC APPROACH TO BACKWARD HEART FAILURE (WET)

Relieve signs of congestion:

1. Abdominocentesis (dog) and pleurocentesis (rarely dog) as required
2. Preload reduction:
   2A–Plasma volume reduction (eg, diuretics such as furosemide, hydrochlorothiazide, spironolactone (especially right HF))
   2B–Venodilation (eg, nitroglycerine, pimobendan)
3. Dietary sodium restriction
4. Inhibition of the rennin angiotensin aldosterone system (RAAS), (eg, angiotensin-converting enzyme inhibitors (ACEI) such as enalapril or benazepril and aldosterone antagonists such as spironolactone)

THERAPEUTIC APPROACH TO FORWARD HEART FAILURE (COLD)

Improve forward cardiac output:

1. Tolerable afterload reduction: Contraindicated in canine subaortic stenosis (eg, ACEI, hydralazine, amlodipine, pimobendan, Na nitroprusside (IV)).
2. Enhance systolic function in diseases characterized by systolic dysfunction such as canine DCM and

CVD (eg, pimobendan, dobutamine (IV), digoxin (weak inotrope)).

3. Treat clinically important (hemodynamically significant) arrhythmias:
   3A–Tachyarrhythmias; Ventricular (eg, lidocaine (IV), procainamide, sotalol, mexilitine, amiodarone), Supraventricular (eg, digoxin, beta-blocker, calcium channel blocker, amiodarone)
   3B–Bradyarrhythmias: Pacemaker, anticholinergics (eg, propantheline bromide), sympathomomemtics (eg, terbutaline), other (eg, theopylline)
4. Treat pulmonary artery hypertension if present and contributing to clinical signs: Phosphodiesterase V inhibition (eg, sildenifil, +/- pimobendan)

THERAPEUTIC APPROACH TO ALL PRECLINICAL AND CLINICAL HEART DISEASE

Agents in this category aim to prolong the preclinical stage in patients with preclinical heart disease and prolong survival in patients with HF.

Delay disease progression (prolong survival):

1. Inhibition of the RAAS:
   1A–ACEI (eg, enalapril, benazepril)
   1B–Aldosterone antagonism (eg, spironolactone)
2. Inhibition of the sympathetic nervous system:
   2A–Beta blockers (eg, atenolol & metoprolol (selective), propranolol (nonselective))
   2B–Adrenergic blockers (alpha & beta blockade), (eg, carvedilol)
3. Other: Modulation of cytokine maladaptation (eg, pimobendan)

PIMOBENDAN BACKGROUND

Pimobendan is a benzimidazole pyridazinone derivative and is classified as an inodilator (i.e., positive inotrope and balanced arteriovenous dilator). In failing hearts it exerts its positive inotropic effects primarily through sensitization of the cardiac contractile apparatus to intracellular calcium. As a phosphodiesterase (PDE) III inhibitor it can potentially increase intracellular calcium

Table 1. Summary of Cardiovascular Medications used in the Management of CVD and DCM

Disease		Preclinical Stage	Clinical Stage
CVD	Sinus rhythm	NT [2], ACEI [2], β-blocker [2]	Diuretic (furosemide) [4]*, Pimobendan [5]*, ACEI [5], spironolactone [4], β-blocker [1]
	Atrial fibrillation or other supraventricular arrhythmias (including sinus tachycardia)	NT [2], β-blocker [2], ACEI [3]	**As per sinus rhythm and add**: amiodarone [4], digoxin [3], β-blocker [3], CCB [2] *Note: combination therapy may be necessary*
	Ventricular arrhythmias	NT [2], β-blocker [3], ACEI [3]	**As per sinus rhythm and add**: sotalol [3], β-blocker & mexilitine [1]
	Left atrial enlargement causing left main stem bronchus compression	NT [2], ACEI [2], β-blocker [2]	**As per sinus rhythm and add**: theophylline SR [4], hydrocodone [3]
	Pulmonary artery hypertension	ACEI [2], β-blocker [2]	**As per sinus rhythm**: ↑ pimobendan dosing frequency to 3 times daily [5] and/or add sildenafil [4]
DCM	Sinus rhythm	ACEI [5]*, β-blocker [3]	Diuretic (furosemide) [4]*, Pimobendan [5]*, ACEI [5]*, spironolactone [4], β-blocker [1]
	Atrial fibrillation or other supraventricular arrhythmias (including sinus tachycardia)	β-blocker [3] + ACEI [4]	**As per sinus rhythm and add**: amiodarone [4], digoxin [3], β-blocker [3], CCB [2] *Note: combination therapy may be necessary*
	Ventricular arrhythmias	ACEI [4], β-blocker [3]	**As per sinus rhythm and add**: amiodarone [4], sotalol [3], β-blocker & mexilitine [1]

For definitions of Preclinical and Clinical disease stages see the preceding text. There is no definitive proof that any medication used during the preclinical stage of DCM or CVD can prolong the preclinical stage, thus the numbers in [ ] represent the authors current recommendations and no therapy (NT) is always an option.

Drugs are listed by class (eg, ACEI) and if there is a preferred drug within a class it will follow in brackets. Each class or specific drug listed is scored between 1 and 5 where [1] means rarely used for the indication and [5] means always used unless there is a clinical contraindication. Diuretic (furosemide) is always used if congestion is or was present.
* denotes which medication should be used if number of medications to be used is limited. This summary is based on professional opinion/experience and currently available peer reviewed data and can be expected to evolve over time.

Abbreviations: Angiotensin-converting enzyme inhibitor (ACEI), beta-blocker (β-blocker), calcium channel blocker (CCB), No therapy (NT).

concentration and increase myocardial oxygen consumption. However, the cardiac PDE effects of pimobendan are reportedly minimal at pharmacologic doses in dogs with heart disease, which is a major advantage relative to other inotropic PDE inhibitors such as milrinone. Pimobendan's calcium sensitization of the contractile apparatus is achieved by enhancement of the interaction between calcium and the troponin C complex resulting in a positive inotropic effect that does not increase myocardial oxygen consumption. Overall, pimobendan enhances systolic function by improving the efficiency of contraction, limiting the arrhythmogenic side effects of other positive inotropes whose sole mechanism of action is to increase myocardial intracellular calcium. Calcium sensitizers such as pimobendan may thus represent the only class of inotropic agents that "safely" augment contractility.

Phosphodiesterase III is found in vascular smooth muscle. Inhibitors of PDE III such as pimobendan result in balanced vasodilation leading to a reduction of both cardiac preload and afterload, a cornerstone of therapy in HF. PDE V concentrations may be higher in the vascular smooth muscle of pulmonary arteries, thus any nonselective PDE inhibition may help ameliorate elevations in pulmonary artery pressure (pulmonary artery hypertension) that tend to parallel long-standing elevations in left atrial pressure, a clinically important complication of CVD.

The significance of alterations in pro-inflammatory cytokine concentrations such as tumor necrosis factor-α, interleukins 1-β and 6 on the progression of HF has been documented in many etiologies of heart disease. Alterations in these cytokine concentrations are associated with increased morbidity and mortality. Pimobendan has demonstrated beneficial modulation of a several such cytokines in various models of HF, representing an additional potential benefit.

PIMOBENDAN THERAPEUTIC RATIONALE

Tolerable reductions in cardiac preload and afterload through balanced venous and arterial dilation are desirable in dogs with HF secondary to either CVD or DCM. The usefulness of "safe" augmentation of contractility is obvious in DCM (because it is characterized by global systolic dysfunction), but is not so obvious in CVD. Dogs with CVD develop compensatory left ventricular remodeling in the form of eccentric hypertrophy (dilation). Left ventricular (LV) systolic function is often thought to be preserved until relatively late in the course of CVD, based on normal or exuberant echocardiographic indices of LV ejection such as fractional shortening. However, interrogation of cardiac function by more sophisticated techniques has demonstrated reductions in LV systolic function in an experimental canine model of mitral regurgitation (MR) and in chronic primary MR of humans, a condition very similar to canine CVD.

Impaired systolic function in cases of HF secondary to CVD may contribute significantly to clinical signs of lethargy and exercise intolerance from reduced forward cardiac output. Although diuretics can relieve signs of congestion, they do little to alleviate and may exacerbate clinical signs of forward HF. Traditionally, dogs with HF secondary to CVD have been managed with judicious afterload reduction using agents such as ACEI alone or in combination with more potent arteriolar dilators (ie, hydralazine, amlodipine). Afterload reducing agents attempt to lessen the differential in pressure between the periphery and the left atrium thereby reducing regurgitant flow resulting in augmentation of forward cardiac output. However, dogs with advanced CVD often do not tolerate afterload reduction well. Frequently, clinical signs of forward HF do not resolve and may be exacerbated by overzealous afterload reduction, further impairing quality of life. Additionally, many dogs with advanced CVD and DCM have severe left atrial and ventricular dilation leading to mitral annular dilation, causing secondary functional MR. Other therapies for chronic valvular disease involve surgical mitral valve repair and mitral annuloplasty; however, these options are not routinely available for canine patients. Furthermore, many dogs with advanced HF due to CVD or other concurrent serious diseases such as chronic renal insufficiency are not good candidates for open-heart surgery even if clients wish to pursue this option.

If a potent positive inotropic agent such as pimobendan could enhance mitral annular and LV papillary tone, thereby optimizing the geometry of the LV and mitral apparatus, functional MR might be reduced leading to augmentation of forward cardiac output, thereby making any concurrent reductions in afterload better tolerated. This combined mechanism of action could be considered a pharmacologic annuloplasty. Reductions in regurgitant fraction may also result in beneficial reverse remodeling (ie, reduction in size) of the LV and left atrium. This constellation of hemodynamic effects may also indirectly modulate neurohormonal systems responsible for the progression of heart failure.

SUMMARY

Pimobendan is a novel agent with properties that are highly desirable in the clinical management of HF secondary to both DCM and CVD in dogs. Review of available data suggests that pimobendan is safe, well tolerated, and leads to enhanced quality of life in dogs with HF secondary to DCM or CVD when used in combination with furosemide or other conventional therapies (eg, ACEI, digoxin, spironolactone). Pimobendan leads to a reduction in mortality from HF associated with DCM and CVD and an ongoing study (QUEST) will offer additional insight into its effects on mortality associated with HF due to CVD.

Chronic valvular heart disease (CVHD) or endocardiosis is the most common acquired heart disease of dogs. Degeneration of the mitral valve characterized by myxomatous proliferation and fibrosis can result in valvular insufficiency and eventually congestive heart failure (CHF). Chronic kidney disease (CKD) is also a common problem that is irreversible and often progressive. Both CVHD and CKD are more prevalent in older dogs and when they occur together, patient management can be challenging. The decreased cardiac output that can occur with CVHD/CHF has the potential to further compromise renal function in CKD patients. Usually the adverse affect of CVHD/CHF is pre-renal in nature but in severe cases, poor renal perfusion can result in additional loss of nephrons, hastening the progression of the CKD. Increasing cardiac output is a major therapeutic goal in patients with CVHD/CHF and the resulting increase in renal perfusion will often also improve renal excretory function.

CHRONIC VALVULAR HEART DISEASE (CVHD)/CONGESTIVE HEART FAILURE

The left atrioventricular (AV; mitral) valve is most commonly affected with CVHD, although in about 30% of cases, the right AV (tricuspid) valve can also be also affected. The disease is approximately 1.5 times more common in males than in females, and it is much more common in small breed dogs. Commonly affected breeds include miniature poodles, chihuahuas, dachshunds, beagles, cocker spaniels, Maltese, Yorkshire terriers, and Shetland sheep dogs. Cavalier King Charles Spaniels (CKCS) are especially predisposed to developing heart failure at a young age from CVHD. The pathologic lesion involves changes in the glycosaminoglycan structure of the intercellular matrix of the valve apparatus (including the valve leaflets and chordae tendinea). These structural changes result in subendothelial thickening and rolling of the valve edges, with eventual deformation of the valve resulting in insufficiency and regurgitation. The prevalence of the pathologic finding increases markedly with age. The factors that cause and/or determine the progression of the lesion are not known; not all dogs with CVHD lesions develop CHF.

Clinical Recognition

The first clinical sign of the disease is the typical murmur of mitral regurgitation, which is usually, heard best at the left apex or midway between the apex and the base. The murmur is typically noted as an incidental finding during routine physical examination. The intensity of the murmur of mitral regurgitation does not always correlate with the hemodynamic significance of the murmur, although in all cases a murmur should be present. In CKCS, it has been demonstrated that the intensity of the murmur generally increases as the mitral regurgitation worsens, probably because the heart gets larger and is acoustically better coupled to the chest wall. This relationship between murmur intensity and severity may not be present in severe heart failure, where the murmur may actually become softer. The presence of a typical left apical regurgitant murmur in a coughing animal does not necessarily mean that the clinical signs present are secondary to CVHD and subsequent CHF, since both bronchial disease and CVHD may exist in the same patient. The patient signalment and history should be examined carefully to try and determine the cause of clinical signs in animals with CVHD murmurs. For example, overweight dogs with no history of weight loss and dogs with marked sinus arrhythmia and relatively slow heart rates are less likely to be coughing due to CHF. Clinical signs of CHF, if present, generally reflect left or biventricular failure and include dyspnea, cough, exercise intolerance, weight loss, and occasionally abdominal distention. Common causes of decompensation in dogs with CVHD include ingestion of a salt load (eg, potato chips), onset of a sustained supraventricular tachyarrhythmia (usually atrial fibrillation), rupture of a chordae tendinea with subsequent worsening of valvular regurgitation, or tearing of the left atrium and subsequent cardiac tamponade.

Modified New York Heart Association Classification (modified from Haggstrom, 2002)

- Class I – Normal activity does not produce undue fatigue, dyspnea or coughing
- Class II – Dog is comfortable at rest but (heavy) physical activity produces fatigue, dyspnea, or coughing; this classification might also include dogs with cardiomegaly but no signs early in this phase.
- Class III – Dog is comfortable at rest but minimal exercise produces signs. Also, orthopnea may exist in this phase.
- Class IV – Congestive heart failure, dyspnea, cough, fatigue, or ascites present at rest.

CHRONIC KIDNEY DISEASE

Nephron damage associated with CKD is usually irreversible and can be progressive. Renal failure results when three-quarters or more of the nephrons of both kidneys are not functioning. Whether the underlying CKD primarily affects glomeruli, tubules, interstitial tissue, or renal vasculature, irreversible damage to any portion of the nephron renders the entire nephron nonfunctional. Healing of irreversibly damaged nephrons occurs by replacement fibrosis and therefore a specific etiology is often not determined. Chronic kidney disease occurs over a period of weeks, months, or years and is an important cause of death in dogs. It is often not possible to improve renal function in CKD and therefore treatment is aimed at stabilizing renal function. Importantly, there is increasing evidence that dietary and antihypertensive treatments can decrease the progressive nature of CKD.

Etiology

The cause of canine CKD is often difficult to determine. Due to the interdependence of the vascular and tubular components of the nephron, the end point of irreversible glomerular or tubular damage is the same. Morphologic heterogeneity between nephrons exists in the chronically diseased kidney with changes ranging from severe atrophy to marked hypertrophy. The histologic changes are not process specific and, therefore, an etiologic diagnosis is frequently not possible. Renal diseases that have been associated with the development of CKD in dogs include glomerulonephritis, amyloidosis, tubulointerstitial disease, pyelonephritis, nephrolithiasis, leptospirosis and neoplasia. Progressive diseases that destroy nephrons at a slow rate allow intact nephrons to undergo compensatory hypertrophy, which can delay the onset of renal failure. Therefore, when renal failure finally occurs, nephron hypertrophy can no longer maintain adequate renal function and less than 25% of the original nephrons are functional.

Staging of Canine CKD

The International Renal Interest Society (IRIS) has proposed a staging system for CKD, which uses serum creatinine concentrations as the major determinate for the staging. As part of the initial diagnosis, serum creatinine concentrations should always be interpreted in light of the patient's urine specific gravity and examination findings in order to rule out pre- and post-renal causes of azotemia. This staging system should only be applied to dogs with stable CKD since in other forms of renal disease (eg, acute renal failure or acute decompensation of CKD); the plasma creatinine concentration can change significantly over a short period of time. In dogs with CKD, staging the disease helps the clinician specifically tailor diagnostic and therapeutic efforts to the individual patient. A guide to staging canine CKD was developed by the IRIS Board (Table 1).

The classic diagnosis of renal failure based on renal azotemia (persistent azotemia superimposed on the inability to concentrate urine) pertains to CKD in later stage II through IV. CKD that is categorized as stage I and early stage II CKD (non-azotemic CKD) could be diagnosed in dogs with persistent proteinuria, urine concentrating deficits, increases in serum creatinine over time that remain in the normal range (eg, serum creatinine that increases form 0.6 to 1.2 mg/dL could indicate a 50% reduction in GFR), or abnormal renal palpation or renal ultrasound findings. The above stages are further classified by the presence or absence of proteinuria and systemic hypertension as shown in Table 2.

Table 1. Guide to Staging Canine CKD Developed by the IRIS Board

Serum Creatinine Concentration	Stage I Non-azotemic CKD	Stage II Mild renal azotemia	Stage III Moderate renal azotemia	Stage IV Severe renal azotemia
mg/dL	<1.4	1.4–2.0	2.1–5.0	>5.0
µmol/L	<125	125–179	180–439	>440

Table 2. Classification of Renal Failure Base on the Presence or Absence of Proteinuria and Systemic Hypertension

Urine Protein/Creatinine Ratio	Classification
< 0.2	Non-Proteinuric
0.2–0.5	Borderline Proteinuric
> 0.5	Proteinuric

Systolic Blood Pressure (mm Hg)	Classification
< 140	Normotensive
140–160	Borderline Hypertensive
> 160	Hypertensive

MANAGING DOGS WITH BOTH CHF AND CKD

Prior to initiating treatment in dogs with CHF, it is important to evaluate renal function. For example, urine specific gravity will be of little diagnostic significance once Lasix treatment has been started. Furthermore, azotemia observed in dogs with CHF is often prerenal in origin and some degree of azotemia (≤30% increase over baseline values) is expected with aggressive management of CHF. When increasing azotemia associated with CHF treatment is of concern, decreasing the Lasix dosage should be the first option pursued.

Managing the patient with both CKD and CVD/CHF requires balancing the tendency to "dry-out" CHF-patients, while "hydrating" those with CKD. These two approaches are often at cross-purposes in the patients under discussion here. Reduction of signs of congestion with for example diuretics lowers cardiac output and thereby renal perfusion, increasing azotemia. In dogs with advanced stage CHF and advanced Stage CKD, strong inotropic support (eg, pimobendan) may be helpful in improving renal perfusion. Hypertension and proteinuria are commonly associated with CKD and complicate the management of these patients and reduce the prognosis. It is now well established that the presence of proteinuria is worsens the prognosis in CKD and is thought by many to contribute to the progression of CKD. Furthermore, systemic hypertension complicates cardiac disease by reducing forward cardiac output. In dogs with CVHD, the detection and correction of systemic hypertension is particularly important because hypertension increases mitral regurgitant flow, in addition to reducing cardiac output, and contributes to the worsening of endocardiosis left atrial enlargement. The latter increases the potential for the development of atrial fibrillation. Because of RAAS and sympathetic nervous system activation, ACEI treatment is foundational for the management of hypertensive and/or proteinuric CKD and CVHD/CHF.

Because anemia is problematic in CHF management in man, presumptively it contributes to the signs and negative prognosis of CHF in dogs. Anemia frequently complicates CKD and as such should be addressed here. There are no data on anemia in cardiac disease in animals to the authors' knowledge but for the motivated client, erythropoietin can improve the quality of life for many dogs with CKD. Because of the potential for binding antibody formation, erythropoietin treatment is usually reserved for those dogs with CKD with weakness and marked lethargy attributable to their anemia. Whether erythropoietin should be used earlier in dogs with both CKD and CVHD/CHF remains to be determined.

Although beyond the scope of this discussion, it is important for the clinician to be aware of the cardiac drugs which are renally excreted and which might require special observation or dosage alteration in cardiac patients with concurrent CKD. Examples of this include digoxin, the ACE-I, enalapril and the beta-blocker atenolol. Each will achieve higher serum levels, though not necessarily harmful, when GFR has fallen in CKD.

The authors' approach to managing and prognosticating various combinations of CKD and CVHD/CHF is outlined below. Key points include:

1. ACE-I remain the cornerstone in the management of CHF and proteinuric and/or hypertensive CKD.
2. Diuresis lowers cardiac output and renal perfusion; therefore will increase BUN and serum creatinine concentrations. If azotemia develops and must be treated, reduction in (or discontinuance) the diuretic dosage should be the first-line approach, with reductions in ACE-I only if necessary. The ACE-I should be reinstituted as soon as feasible, with diuretic use following only as needed.
3. Much of the azotemia observed in CHF-treated dogs is largely pre-renal and, as such, treatable. A certain degree of azotemia may be necessary in the treatment of CHF.
4. Treatment must balance the traditional "drying" efforts of CHF-management with the "hydrating" efforts used in CKD.
5. Rehydration should include relatively salt-poor fluids in dehydrated and azotemic patients with CVHD/CHF.
6. Hypertension worsens both CVHD/CHF and CKD. As such, it should be sought out, recognized and managed.
7. Pimobendan, in addition to being a new and important new drug in our treatment of CHF, may help us to improve renal perfusion, reducing azotemia in cardiac patients.
8. Proteinuria worsens the prognosis of CKD. It should be monitored and treated (ACE-I).
9. CKD may affect the excretion of cardiac and other drugs. The dosage of these drugs should be adjusted as necessary.
10. The prognosis for true renal failure (IRIS Phase 4 CKD) and severe CHF (NYHA Phase 4) is poor.

PATENT DUCTUS ARTERIOSUS: NEW TREATMENT OPTIONS

Henry W. Green, III, DVM, Dipl. ACVIM (Cardiology)
School of Veterinary Medicine
Purdue University , West Lafayette, IN

Patent ductus arteriosus (PDA) is one of the most common congenital heart defects in dogs and is associated with profound hemodynamic alterations. It results from a failure of the left sixth aortic arch to close following birth allowing blood to shunt from the descending aorta into the pulmonary artery when body pressures are normal. The resultant left to right shunting leads to volume overload of the left heart and subsequent congestive heart failure if left untreated. Poodles, collies, Pomeranians, Shetland sheep dogs, Maltese, English springer spaniels, keeshonds, and Yorkshire terriers are all considered to be predisposed to having PDA. German shepherds and New Foundland dogs are two large breeds that also commonly present with PDAs.

DIAGNOSIS

The diagnosis of PDA usually can easily be made based on physical examinations findings. Auscultation of a continuous heart murmur over the left cranial thorax in the left axillary region and the femoral pulses are hyperkinetic. A secondary systolic murmur over the left 4th to 6th intercostal space may also be ausculted and is often due to mitral regurgitation the is the result of mitral annular dilation. Other physical examination findings might include signs consistent with left sided congestive heart failure including increased lung sounds, crackles and wheezes. Beyond physical examination other diagnostics such as electrocardiogram, radiographs, and echocardiogram are used to confirm suspicion based on the physical exam and to rule out other congenital heart defects that might complicate the treatment. Some common abnormal findings based on these diagnostics are listed below.

- **Electrocardiography**
  - Sinus tachycardia, atrial premature complexes, or atrial fibrillation
  - +/- Signs of left ventricular (LV) and/or left atrial (LA) enlargement
- **Thoracic radiography**
  - Left ventricular, +/- atrial enlargement
  - Pulmonary overcirculation – enlarged pulmonary arteries and veins
  - The classic "Ductus bump"
  - Dilation of the main pulmonary artery (PA)
  - Pulmonary venous congestion and pulmonary edema
- **Echocardiography**
  - LV, +/- LA dilation
  - MPA dilatation
  - Visualize the ductus
  - Reduced percent fractional shortening (%FS)
  - Continuous retrograde flow in the PA, +/- mitral regurgitation (MR), +/- pulmonary insufficiency (PI)
  - Exaggerated aortic flows

We also utilized echocardiography to get a preliminary idea of the size of the ductus so that we can plan the appropriate treatment options.

Definitive therapy for PDA involves closure of the ductus. Traditionally in veterinary medicine, surgical ligation of the ductus via lateral thoracotomy is highly successful for correction of this defect. However, surgical options have been associated with increased morbidity, and arguably increased hospital stays and cost compared with newer transcatheter techniques. Since its first reported use in dogs in the late 1990s; transcatheter measurements have become a popular and successful alternative to surgery among veterinary cardiologist, paralleling the trend in human medicine. It is important to remember with new techniques comes new growing pains in the search for the ideal device to "replace" the surgical gold standard. Ideally this device would satisfy most of the following criteria: It could be delivered via a small catheter to suit our small patients, delivery could be controlled to allow repositioning of the device and could be retrievable, it would provide complete occlusion with no obstruction to normal flow, it could be used in the different morphologic forms of PDA, and it would be comparable to if not better than surgery as it pertains to complications and cost. A number of techniques and devices have been developed and used over the years; however, three devices have proven to be the most amendable for therapy for canine PDA: vascular occlusion coils, the Amplatz vascular plug, and the Amplatz canine vascular occlusion device.

While transcatheter closure of the PDAs requires specialized equipment and training and is not performed in general private practice, it is imperative for the private practitioner to have a basic understanding of treatment options, their outcomes and complications to provide the most essential information to their clientele regarding treatment options for this disease.

ANGIOGRAPHIC MORPHOLOGY

Under fluoroscopic guidance, specialized catheters are placed into the aorta to perform angiography of the ductus to further assess ductal shape and size. The different angiographic morphologies seen in veterinary medicine usually fall into the general classification scheme below as described by Miller et al. This helps us to confirm which device will be best suited for closure of the ductus. While most of these devices will work we do feel some work better with different ductal morphologies (Table 1).

Table 1. Types of Canine Patent Ductus Arteriosus

Type I	Type IIa	Type IIb	Type III
Narrow ductus with a constriction at the pulmonary ostium	Funnel shaped (wide aortic side) ductus that narrows toward to pulmonary ostium	Funnel shaped short ductus that narrows at the pulmonary ostium	Tubular shaped ductus with **NO Narrowing** at the pulmonary ostium

CATHETER-BASED THERAPY

Over the past 15 years the most commonly used device to accomplish this was the **Gianturco vascular occlusion coil** (Figure 1). Coil embolization was first described in veterinary medicine in the mid 1990s. Coils are made of a double helix stainless still wire with Dacron fibers attached, which induces clot formation within the ductus. Several techniques have been described for coil deployment into the ductus via transvenous or transarterial route. In typical cases, we use a modified myocardial bioptome transcatheter system, via the femoral artery, that allows controlled release of coils into the ductus using fluoroscopic guidance. This controlled release of the coil device reduced the risk of coils embolizing to the pulmonary artery or aorta. However, this system is limited to dogs large enough to accept this system within the femoral artery and has grown to be a somewhat expensive technique as the price of the bioptome used for this method has significantly increased. To expand our ability to occlude PDAs via transcatheter route, we have also described a coil free-release deployment protocol for dogs too small to have the bioptome system placed into their femoral artery. With this technique we have closed PDA in dogs as small as 0.7 kg in size. The main limitations to coil therapy are ductal diameter and morphology. Animals with large ductal diameter of the pulmonary ostium (ie, >3–4 mm) or type III ductal morphology were apt require multiple coils, experience incomplete closure or have coils embolized to the lungs. However, we have found high success using coils in small dogs with small-diameter PDAs or dogs large enough to be able to utilize a controlled release system. A number of other release techniques have also be described with a significant amount of success.

In our experience we found a similar to decreased complication rate utilizing coil techniques. Our overall complication rate of our first 100 coil attempts was approximately 7%, which was comparable to early surgery attempts here at Purdue University (9%). Complications included pulmonic and rarely (2 cases) aortic embolization of the coil, incomplete closure of the ductus, and in two cases death that we could directly attribute to the procedure. Also it on several occasions it would be necessary from multiple coils to be placed in a single or subsequent procedure which increased cost of the procedure and anesthetic times. Because the overall goal of any new, “less invasive” technique is or should be to improve upon the goal standard- surgical closure we felt coils were good but not good enough.

Thus, we came across the **Amplatz Vascular Plug** which is a self-expandable, cylindrical device made from a Nitinol wire mesh (Figure 2). It is securely attached to a threaded delivery cable which is unscrewed from the device when satisfactory placement is attained. This device was originally designed for arterial or venous embolization in the peripheral vasculature of human. The device size ranges from 4 to 16 mm in diameter. Use of this device for closure of PDA’s in veterinary medicine was first described by Purdue University Cardiology in 2005. The device comes in numerous sizes and is seated in the ampulla portion of the ductus causing physical obstruction until clot formation occurs. The device selected is typically 1.5 times the distal ductal

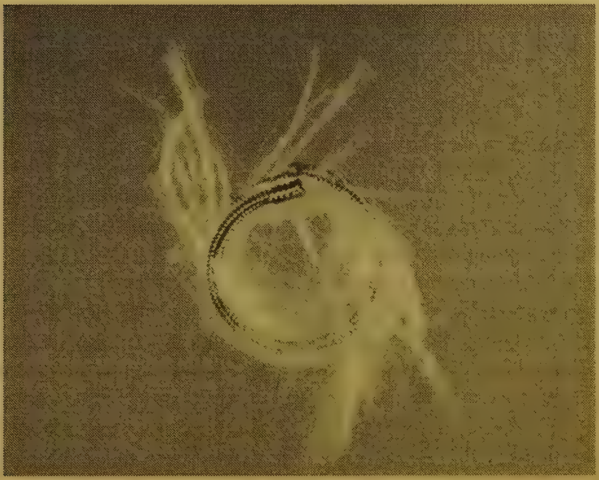

Figure 1. Gianturco vascular occlusion coil.

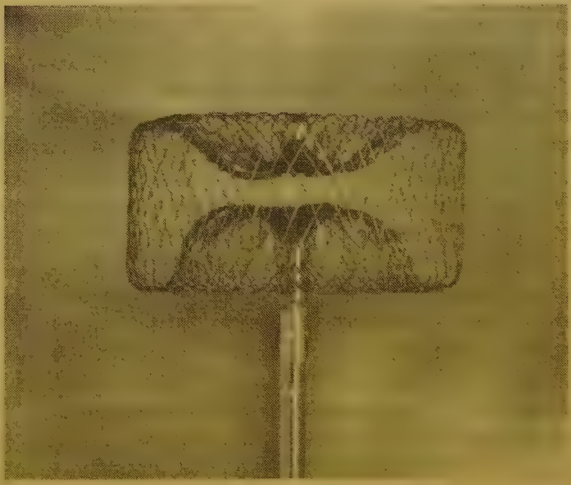

Figure 2. Amplatz Vascular Plug.

diameter. Often complete closure takes about anywhere from 5 to 15 minutes. In our experience this device is very successful as we have successfully obtained complete closure in approximately 98% of the cases in which we elected to use the PLUG device. We have experienced only one embolization of this device to the lungs in an early attempt to close a type III ductus. No subsequent negative affects were noted in this patient. No other "major" complications have been experience by our group when utilizing the plug. A minor complication, incomplete closure of the ductus has, occurred in only one case where we used an undersized device, less than 1.5 times the size of the distal ductal diameter. Currently, in our experience, it appears that this device is best suited for use in long tubular shaped PDAs such as Miller type I morphology. It appears to be limited in short type IIb PDAs as the length of the device may cause partial aortic deployment and also in type III PDAs as the diameter of these PDAs often exceeds the largest diameter device. One main large advantage of the plug is its ability to be deployed via the transvenous in addition to transarterial routes. In particular, this deployment route benefits small dogs with diminutive femoral access that also had "larger" PDA minimal diameters that would be best suited for a controlled release device. In these cases, we obtain venous access via the external jugular vein that typically allows large enough access to place the appropriate sized catheters through which a plug could be positioned into the ductus in retrograde approach. We have successfully used the transvenous route in 3/3 cases this was indicated.

The latest device used for closure of PDA is the **Amplatz Canine Duct Occluder (ACDO)** which is a self-expanding device made of a multi-layered nitinol wire mesh that was uniquely designed for closure of canine PDA's (Figure 3). Successful use of this device was first reported also in 2005 by University of Minnesota cardiology in 10 of 11 dogs. Uniquely, this device has a distal flat disk is that is placed on the pulmonary artery side of the ductal opening and a cup-shaped proximal portion that is deployed into the ductal ampulla. As the device is implanted, the proximal cupped portion conforms to the shape of the ductal ampulla with the waist of the device spanning the ductal pulmonary ostium to provide a secure fit. The device is detachable as it is preloaded onto a threaded delivery cable. The device can fit a number of sizes as it is available in 3-mm to 14-mm waist. We have enjoyed a 100% success rate with this device in 26 cases that we have elected to use it in. The shape of the cup portion of this device conforms nicely to the funnel shape of the ductal ampulla of type II PDA but this does not limit the devices use to that specific morphology. We have not attempted use in type III PDAs and based on its mechanism of security across the ostium it does not appear to be a suitable device for this morphology. The main limitation in our experience for those cases where the ACDO was indicated is that it can only be delivered via the transarterial route. Thus, it may not be amendable to use in very small dogs with larger than expected PDA diameters whose arterial access is too small to accept a 5 French catheter system (the smallest delivery system for this device).

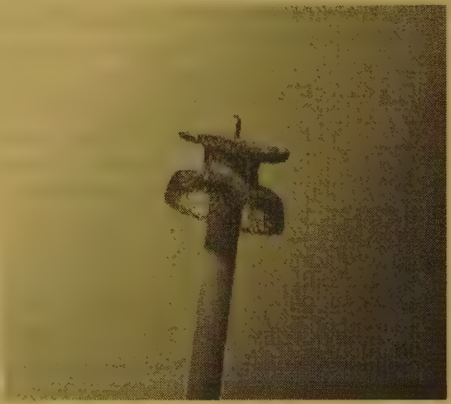

Figure 3. Amplatz Canine Duct Occluder.

While all three devices have some limitations we have had high success rates in utilizing all three devices. Overall, transcatheter PDA occlusion has the advantage that it is much less invasive than surgery. Although anesthetic time may be similar in some cases there is significantly reduced postoperative morbidity associated with transcatheter occlusion. This allows for much quicker recoveries as our patients usually are released from the hospital the day after the procedure barring any unforeseen complications. The concept of the ideal device that fits every circumstance for transcatheter closure of PDA is most likely an unrealistic one. More and more we are realizing that there is a role for all three devices and it is our practice to keep all three supplied and make the correct selection based on patient size, angiographic morphology of the patient's PDA, and the size of the pulmonary ostium or the distal ampulla. This gives our patient the best shot at having a successful transcatheter closure performed. For dogs with type III morphology, surgical closure remains the gold standard of therapy.

FELINE CARDIOMYOPATHIES: WHAT DO WE DO FOR THERAPY OF THROMBOEMBOLIC COMPLICATION

Henry W. Green, III, DVM, Diplomate ACVIM-Cardiology
Purdue University School of Veterinary Medicine
West Lafayette, IN

Thrombotic and thromboembolic complications have long been recognized as some of the most difficult to manage complications of feline myocardial disease. This syndrome is often referred to as feline aortic thromboembolism (FATE). Thrombosis represents clot formation within a cardiac chamber or vascular lumen. Thrombus formation has been historically linked to the presence of one of three predisposing factors known as *Virchow's triad*: 1) local vessel or tissue injury, 2) circulatory stasis, and 3) altered blood coagulability. These thrombi typically form in the left atrium, left ventricle or both. Embolization occurs when a clot fragment or other foreign material lodges within a distal vessel. Although the distal aorta is the most common site of embolization, various other organs (ie, the kidney, intestine) may become affected during embolic showers.

The prevalence of thromboembolism has been widely reported. In studies of FATE in necropsied cats, thromboembolism was seen in up to 48% of cats with hypertrophic cardiomyopathy (HCM), 29% with restrictive cardiomyopathy (RCM) and 25% with dilated cardiomyopathy (DCM). The prevalence in clinical settings obviously; is much less, being reported from a range of 12% in HCM cats to 18% in taurine deficient DCM cats. In recent clinical study FATE was seen in 0.57% of all feline clinical cases seen at a single referral institute. Incidentally, FATE is rarely seen in cats with hyperthyroidism; it has only been reported in 2% and 3% of cats in retrospective studies of cats with thyrotoxicosis.

CLINICAL PRESENTATION AND EVALUATION

The clinical presentation of cats suffering FATE may vary substantially depending on the location of the thrombus, the extent and duration of arterial occlusion, the degree of functional collateral circulation, whether the cat is suffering from concurrent congestive heart failure (CHF), and the development of other severe complications such as renal failure. Classically cats will present with paralysis, paresis, and painful; firm cold limbs and pale footpads, along with pale or cyanotic nail beds and potentially very weak to nonpalpable femoral pluses. Clinical signs are attributable to substantial tissue injury (ischemic neuropathy) due to the sudden arterial occlusion with almost instantaneous and complete interruption of blood flow, coupled with decreased collateral circulation secondary to vasoconstrictive substances being released from the thrombus.

If FATE is suspected based on clinical presentation, a minimum data base should include a complete blood count, coagulation and biochemical profiles; urinalysis, blood pressure, thoracic radiographs, electrocardiogram, and echocardiogram. Common clinical pathology abnormalities include elevated blood urea nitrogen (BUN) and creatinine, elevated serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST) as well as increases in creatine phosphokinase (CPK). Hyperglycemia, and stress leukogram characterized by a mature neutrophilia and lymphopenia may also be present.

Thoracic radiographs are indicated to assess for cardiomegaly and CHF. Echocardiography gives a non-invasive assessment of cardiac structure and function. It also allows for investigation of the cardiac chambers for thrombi and spontaneous contrast (smoke) which is believed to result from blood stasis and subsequent rouleaux formation of red blood cells. Smoke may be present in the LA or LV and is a harbinger for thromboembolic potential.

MANAGEMENT OF FATE

Treatment of acute FATE should address general patient support; management of concomitant CHF and/or arrhythmias, and thrombus therapy to limit thrombus growth and formation. Chronic therapy is aimed at prevention of repeated thromboembolic events.

Analgesic therapy is essential for cats with FATE to alleviate pain, discomfort and stress associated with the ischemic myopathy during the first 24 to 48 hours following a thromboembolic event. Butorphanol, morphine, oxymorphone and fentanyl have all been used for this purpose. Maintenance of hydration, electrolyte balance and nutrition is also important during the first days of therapy. Thus it may be necessary to place nasoesophageal feeding tube, particularly when CHF has been resolved but there is persistent anorexia present.

Thrombolytic therapy with **streptokinase** and **urokinase** or with **tissue plasminogen activator (t-PA)** can be attempted within the first few hours of a thromboembolic event in attempt to lyse the clot and rapidly restore perfusion to affected limbs. Therapy with these agents has not gained as great of popularity in veterinary medicine as has been seen in human medicine. The expense associated with their use, the need for emergency availability and difficulty found in using these drugs as well as managing related complications in cats have all led to their minimal utilization veterinary medicine. We currently only use these drugs on rare occasions.

Anticoagulant therapy has been a mainstay of therapy for thromboembolic disease. Anticoagulants work by retarding the synthesis or accelerating the inactivation of clotting factors but they have no effect on established thrombi. Their use is therefore based on the premise of prevention of thrombus formation or preventing thrombus extension resulting in subsequent further reduction in arterial blood flow. **Coumarin (warfarin)** impairs hepatic vitamin K metabolism, thereby interfering with production of the procoagulant factors II, VII, IX and X Given the lack of evidence of preventing thromboembolism as well as the difficulty associated with monitoring these patients, and the potential for complications; wafarin therapy has not really gained favor in the treatment of this disease. **Heparin** has also been used as acute and chronic anticoagulant therapy in cats. Heparin also binds and inhibits von Willibrand factor thus exhibiting some direct antiplatelet effects. Classically unfractionated heparins (UFH) have been used for this purpose. **Low-molecular-weight heparins (LMWH)** are fractionated particles of heparin that are now available and have greater bioavailability, a longer plasma half life than UFH and can reportedly be given as a fixed subcutaneous dose once daily however most pharmacokinetic studies of this drug suggest the need for more frequent 2 to 3 times a day dosing. The problem with these studies however is the endpoint that was being studied prolongation of anti factor Xa has not been proven to necessarily correlate to preventing thrombus formation. Thus studies need to be performed that directly assess dosing affects on clot formation or prevention thereof.

Antiplatelet aggregating drugs are used to prevent the activation of platelets in response to exposure of blood to subendothelial connective tissue. **Aspirin** has traditionally been used in this manner as it induces a functional defect in platelets by irreversibly inactivating cyclo-oxygenase. Although aspirin should theoretically be beneficial, there is no evidence that aspirin is effective at preventing first time or recurrent thromboembolism. Also there is recent research that questions the ability of aspirin to decrease platelet stimulation and aggregation or to suppress overall thromboxane A_2 production. Current research with aspirin is focusing on the use of low dose aspirin (5 mg/cat every 72 hours) base of the theory of sparing endothelial prostaglandin I_2 synthesis. Newer antiplatelet drugs include the thienopyridine derivatives **ticlopidine** and **clopidogrel**. They function by irreversibly binding ADP to its receptor on platelets, thereby preventing the transformation of the IIb/IIIa glycoprotein receptor to its active form. Clopidogrel, however, effectively inhibited platelet aggregation with no apparent gastrointestinal side effects when dosed at 18.75 to 75 mg/cat/day PO. Current trials with clopidogrel are ongoing at Purdue University to assess drug efficacy versus aspirin in the FATCAT study.

SO WHAT DO WE DO WITH OUR PATIENTS?

Acute Stage

Supportive care is the mainstay of our treatment: Pain management and control signs of congestive heat failure – if present. Owners are offered the option of thrombolytic therapy.

A loading dose of clopidogrel 75 mg is given if the blood work is relatively normal along with a loading dose of unfractionated or low-molecular-weight heparin.

Chronic Stage

Depending on the cat's status (to be discussed further), chronically we recommend clopidogrel (Plavix®), 18.75 mg PO every 24 hours. We also commonly will use chronic therapy with LMWH. We commonly utilize these drugs in combination as they could offer synergistic effects of preventing clot formation. In such cases, we often use dalteparin 100 UI/kg every 12 hours or enoxaparin 1 to 1.5 mg/kg every 12 hours SQ.

Preventative

Cats that appear to be at risk for FATE (ie, thrombus, or spontaneous contrast of those with large diameter LA are seen on echocardiogram) we suggest starting therapy with clopidogrel (Plavix®) 18.75 mg PO every 24 hours.

OUTCOMES

Honestly, we do not truly have a handle on outcomes of these patients. We know poor prognostic indicators include hypothermia on presentation in the acute stage, thrombus present in the LA, and signs of renal dysfunction along with congestive heart failure. Historically most studies assessing survival of acute episodes report a 33% to 39% rate of survival to discharge. These numbers may be skewed significantly since this represents data mostly from referral institutions where cases may be significantly more severely affected. More recent data suggest improved survival rates with up to 73% of cats being discharged after acute events. Because prospective, double-blinded, placebo-controlled trials evaluating secondary prevention of CE are lacking, specific conclusions regarding efficacy of individual antithrombotic agents cannot be made. The Feline Arterial Thromboembolism; Clopidogrel vs. Aspirin Trial (**FAT CAT**) was designed to be the first prospective study to evaluate antithrombotic therapy for the secondary prevention of CE in cats. This study will hopefully give us some idea further insight into outcomes with this tragic disease and research efforts on the causes and prevention of thromboembolic disease may help to improve the survival figures in cats with cardiomyopathy.

FELINE SYSTEMIC HYPERTENSION: DIAGNOSIS AND TREATMENT

Henry W. Green, III, DVM, Dipl. ACVIM – Cardiology
School of Veterinary Medicine
Purdue University, West Lafayette, IN

It has become increasingly apparent that systemic hypertension affects a large number of cats, resulting in significant clinical disease. It is important to be able to determine when systemic hypertension is present so appropriate therapy can be instituted to reduce or prevent severe consequences. Techniques are constantly being refined to measure blood pressure, as is our understanding of what "normal" blood pressure is in cats.

ETIOLOGY AND PATHOPHYSIOLOGY:

Cardiac output (CO) and systemic vascular resistance (svr) are both important in determining arterial blood pressure (MAP = CO X svr). Cardiac output itself is further determined by stroke volume (SV) and heart rate (HR) (CO= SV x HR). Thus, any disease state that affects CO, HR, SV or svr can result in systemic hypertension. Increased sympathetic tone and hyperthyroidism are common causes of increased heart rate. Stroke volume is increased with plasma volume expansion secondary to activation of the renin-angiotensin-aldosterone system (RAAS), increased dietary sodium, and increased arginine vasopressin (ADH). Increased svr is associated with increased RAAS, sympathetic nervous system (SNS), ADH, endothelin (ET-1), reduced nitric oxide (NO) production, and microangiopathic diseases (diabetes mellitus) or as a common pathway as a vascular response to continued elevated blood pressure.

While the most common cause in people is considered "essential" or idiopathic, this should not infer that there is no underlying cause. In people essential hypertension is often associated with some form of renal disease that results retention of sodium and water, alterations in the RAAS, SNS hyperactivity, Atrial natriuretic peptide (ANP) resistance, reduced clearance of vasoactive substances and reduced production of vasodilating substances (ie, NO or prostaglandins). In people, two principal theories for sodium and water retention with renal disease are: 1) resetting of the pressure-natriuresis relationship such that it takes a greater elevation in renal afferent arterial pressure to get the same degree of sodium excretion or 2) the nephron heterogeneity or ischemic nephron theory which states that there is a heterogenous population of ischemic and nonischemic nephrons. The ischemic nephrons have in creased renin release that induces increased sodium and water retention from the nonischemic nephrons thereby causing an increase in vascular volume and because there are only a small number of ischemic nephrons there is not a detectable increase in renin concentration within the systemic circulation. While these and a number of other theories abound and there have been billions of dollars spent in research in people the exact mechanism continues to elude researchers.

In cats, systemic hypertension is most commonly associated with chronic renal disease and hyperthyroidism with a reported incidence of 60 % to 69% in chronic renal disease and 80% to 89% in hyperthyroidism. There is much less known about the association of chronic renal disease and systemic hypertension association in cats compared with human medicine. Other known relationships include primary hyperaldosteronism, acromegaly, diabetes mellitus, and unknown. In most causes however, the diagnosis of systemic hypertension is only made once there is significant elevation and related severe clinical signs.

CLINICAL CONSEQUENCES

Organs that have an abundant arterial and arteriolar supply tend to have the most notable consequences of systemic hypertension theses include the brain, eye, kidneys and the heart. The vascular responds to chronically elevated pressures by smooth muscle hypertrophy within the medial layer to cause reduction in wall stress. If the increased pressure does not subside however, the vascular walls become fatigued and elastin molecules fracture, develop fibrous metaplasia and leak plasma resulting in hyalinization with resultant smooth muscle necrosis. This eventually results in reduced vascular compliance, which is a long lasting affect and can be irreversible forming the final common pathway for uncontrolled systemic hypertension.

Ophthalmologic Effects

Retinal blood flow is strongly controlled by autoregulation. Prolonged exposure to elevated systemic pressures results in leakage of blood and plasma causing retinal edema, retinal hemorrhage and accumulation of fluid in the subretinal space with subsequent retinal detachment. The choroidal vascular bed appears to be primarily affected by hypertension in cats. Damage to this vascular bed results in necrosis and atrophy of the retinal pigmented epithelium and ischemia to the outer retinal layer. These alterations are responsible for the high incidence of complete retinal detachment seen with cats affected with systemic hypertension.

While acute blindness is the most common clinical sign associated with hypertensive retinopathy in cats, this occurs very late in the course of the disease with more subtle signs missed by the owner. Common ophthalmologic findings include retinal vessel tortuosity, retinal hemorrhages, blood within the vitreous humor, hyphema and focal or complete retinal detachment. While complete retinal detachment is still associated with a poor to guarded prognosis, there are some cats that regained vision after successful antihypertensive treatment.

Central Nervous System (Brain)

Cerebral blood flow is determined by systemic pressure and is also under autoregulatory control of the arteriolar beds. The beds vasoconstrict or dilate in response to elevated or decreased systemic pressures respectively to maintain a relatively constant cerebral blood flow. Constant vasoconstriction of these vessels results in fibrinoid necrosis that can lead to decreases in blood flow, thrombosis, and ischemia, loss of vascular integrity, hemorrhage, edema and infarction. Clinical signs can include depression, dementia, stupor, and seizures. Acute hemorrhage or edema can results in rapid clinical deterioration.

Renal

Renal flow just like those above is also under autoregulatory control with a very constant range by the renal afferent arterioles. Chronic elevation of systemic pressures outside of the normal operating range of autoregulation results in damage to the afferent arteriole. This results in a less responsive arteriole to alterations in systemic pressures that dilates and leads to progressive glomerular hypertension and renal injury. As in humans, it has been well documented that uncontrolled systemic hypertension is associated with progressive renal disease; therefore, it is often difficult if not impossible to determine where an individual patient falls within the vicious cycle.

Cardiovascular

Elevated systemic pressures result in increased left ventricular afterload and wall stress. The myocardial response to this abnormal pressure is concentric hypertrophy, which is an attempt to bring the left ventricular wall stress back to a normal despite the elevated afterload. Although the wall stress returns to normal, there is an increase in cardiac work and oxygen demand by the myocardium. The hypertrophy of the myocardium is accompanied by remodeling of the interstitium characterized by excessive collagen production that is theoretically under the control of angiotensin II, aldosterone, transforming growth factor-β, platelet derived growth factor, tumor necrosis factor α , interleukins-1 and -6, and others. The increased fibrosis results in loss of ventricular compliance and forms the basis of diastolic heart failure.

The vascular changes (medial hypertrophy, fibrous metaplasia, hyalinization, edema, necrosis and sclerosis) occur are seen in most vascular beds. In addition, the coronary flow is also affected and results in less vasodilatory capability reducing coronary flow reserve. The increased workload combined with the reduced ventricular compliance and reduced coronary reserve results in altered myocardial oxygen demand/oxygen supply relationship that increases the risk for myocardial ischemia, infarction, arrhythmias, heart failure and sudden death.

Clinical findings related to the cardiovascular system are common in cats with systemic hypertension. Cardiomegaly and tortuous aortic arch can be seen in thoracic radiographs along with the pattern of left anterior fascicular block on surface electrocardiography however, these are not specific to systemic hypertension. Echocardiography often shows mild to moderate left ventricular concentric hypertrophy with minimal left atrial changes. Congestive heart failure secondary to systemic hypertension appears to be very rare in this author's experience unless concurrent cardiac disease is present.

DIAGNOSIS

Measurement of blood pressure can be done one of two ways. One direct measure by inserting a needle or catheter into the arterial system is the "Gold Standard." While this is a very accurate and simple method, it does require specialized equipment, experience and is not practical for repetitive measurements that are necessary for monitoring. Because of these limitations the indirect method of blood pressure measurement has become the most accepted and widely used method on a daily basis. There are three methods commonly used to measure blood pressure indirectly; Doppler, oscillometric and photoplethysmographic.

Doppler

This method utilizes Doppler shift principles of sound. Essentially, as the moving blood passes the piezoelectric crystal of the unit a sound is generated. The crystal should be placed over a peripheral artery (dorsal pedal, palmar or plantar) or the base of the tail to achieve a good audible signal. A pressure cuff is then wrapped around the limb proximal to the crystal and inflated until the signal of blood flow is lost. Pressure is then slowly released from the cuff until the audible signal of blood flow is just heard. The pressure reading at the point where the audible signal becomes apparent again is the systolic pressure. The Doppler technique is only able to accurately measure systolic pressure. The diastolic pressure can be estimated by the sound of change as the pressure continues to drop but this is very inaccurate. This has been the best technique for cats. There are a number of newer devices that are challenging this belief.

Oscillometric

The oscillometric method evaluates the oscillation in an air bladder (cuff) to measure blood pressure. Only the systolic pressure is truly measured. Both the diastolic and mean pressures are calculated values. These machines will also record pulse rate. The cuffs have an arrow indicator that should be placed over the artery that is to be used. Most machines are automated and the simple push of a button is all that is needed. While these units have historically performed better in dogs and larger animals there are some that have shown better function in cats although in this author's opinion Doppler techniques still remain best suited for cats.

Photoplethysmography

This commonly used method in human medicine is rarely used in veterinary medicine despite one study stating it accuracy and reproducibility. With this technique, the change in density of the blood circulating in the capillary beds beneath the skin is detected by infrared light. Calculations are made based on these changes so systolic, diastolic and mean pressures can be recorded. Additionally pressure waveforms are generated that can be displayed on the monitor.

Regardless of the technique used, certain steps should be followed in order to improve the accuracy of your blood pressure reading. The readings should be taken one the cat is in relatively calm state and away from loud noises, other animals and distractions. The artery should be at the same height as the heart and the width of the cuff should be about 40% of the circumference of the limb. Because of the well recognized 'white coat effect' on blood pressure, measurements should be repeated from 3 to 10 times with the average of these readings used as the recorded measurement. For purposes as a guided, this author recommends the following example of pressure assessment: We typically consider a pressure of 170 mmHg to be normal in a cat in the clinical setting. If a cat has a systolic pressure of 190 mmHg and the above steps have been taken, then we consider this cat to have systemic hypertension. If a cat has a pressure reading between 170 and 190 mmHg and has clinical signs (renal insufficiency, retinal lesions, neurologic signs) then we consider that cat hypertensive and suggest treatment. If no clinical signs are present, we suggest close, frequent monitoring of blood pressure for this patient.

Cats diagnosed as hypertensive should have extensive exams for the underlying cause of the hypertension since majority of hypertensive cases are secondary in nature. Cats should have renal function and electrolytes evaluated as well as thyroid status. Ophthalmic exams should also be performed on all suspects.

TREATMENT

Concurrent treatment of underlying causes is a critical component to successful control of blood pressure. Hyperthyroid cats should receive antithyroid treatment along with an antihypertensive drug. Chronic diseases such as renal disease and diabetes mellitus should be adequately treated. Failure to provide such concurrent treatment will often result in inadequate pressure control. Prolonged antihypertensive therapy may be necessary even after reversible causes of hypertension (ie, hyperthyroidism or primary aldosteronism) have been treated due to the small vessel disease that develops with chronic hypertension.

Vasodilators

Currently these agents are the mainstay of hypertensive therapy in cats. Their use results in precapillary arteriolar dilation thereby reducing systemic pressures. The two main classed of vasodilation agents used in cats are the dihydropyridine calcium channel blockers (CCB) and the angiotensin converting enzyme inhibitors (ACE-I).

Dihydropyridine Class of Calcium Channel Blockers (CCBs)

These drugs induce significant arteriolar smooth muscle relaxations with little central (heart) electrophysiologic effects. These are potent arterial vasodilators and have been proven to be very effective in feline hypertension from any cause. There is often concern that these agents may predispose the kidney to glomerular hypertension due to renal afferent arteriolar vasodilation. However, the concurrent reduction in systemic pressures may counterbalance this effect and in human studies results demonstrate equivalent reduction in Proteinuria when compared to ACE-Is. The CCBs are currently our first choice for feline hypertensive patients.

- **Amlodipine** (Norvasc®) – 0.0625 mg/cat PO q 24 hrs (< 5 kg)
    - o 0.125 mg/cat PO q 24 hrs (> 5 kg)

Angiotensin Converting Enzyme Inhibitors (ACE-I)

These agents reduce the amount of angiotensin II (ANGII) produced through RAAS. Angiotensin II induces sodium and water retention and is a potent vasoconstrictor. These agents have been very effective in human patients and have displayed renoprotective properties and they are recommended with clinically significant proteinuria. Unfortunately, these agents seem to have limited effectiveness in treating hypertensive cats for two main reasons: 1) RAAS does not appear significantly elevated in chronic renal disease or hyperthyroidism and 2) cats (and dogs) are generally less responsive to the vasoactive properties of the ACE-I when compared with humans. Thus, this class is usually our second choice:

- **Enalapril** (Vasotec®, Enacard®) – 0.25–0.5 mg/kg PO q 24-12 hrs
- **Benazepril** (Lotensin®) -- 0.25–1 mg/kg PO q 24 hrs

For any undergoing treatment for hypertension, frequent indirect monitoring is essential. This should be weekly or biweekly until goal pressures of 120 to 170 mmHg are attained. Other common additional protocols such as timing and use of α-receptor (prasozin) and β-receptor blockers and the potential role of diuretics will also be discussed.

Feline systemic hypertension is s common clinical disease that needs to be monitored for and its prevalence and devastating consequences should increase the use of blood pressure monitoring equipment in all veterinary practices.

NEW TEST FOR FELINE CARDIOMYOPATHIES

Henry W. Green, III, DVM
Diplomate ACVIM (Cardiology)
School of Veterinary Medicine
Purdue University, West Lafayette, IN

The prospect of biochemical screening of cats for heart disease is a very attractive prospect. This is a very exciting endeavor in that it could allow individuals without extensive training in cardiology and echocardiography to identify animals with heart disease more accurately and at an earlier point in the disease process. If successful such testing could allow for the delivery of early treatment and aid in the clarification of equivocal test results. The ability to screen cats for the potential of heart disease may also be especially helpful to detect those cats at risk for heart failure when anesthesia or fluid therapy is indicated which often results in the development of congestive heart failure.

While the prospect of biochemical testing is an exciting one, filled with possibilities we must be careful in how these test which will likely become available at some point, is used. One it should be recognized that these test most likely will be used as an aid to identify those who need further advanced testing and not a replacement for advanced testing. Also we must identify test for screening that has a very high sensitivity and at least a reasonable level of specificity (i.e. it should detect at least 90% of the target group and likely a specificity of 70%).

POTENTIAL TARGETS

Cardiac Troponins

The cardiac troponin complex is composed of three subunits (I, T, and C) that regulate the excitation-contraction coupling of the sarcomeric proteins. Injury to cardiac muscle induces release of these subunits into the circulation where their levels are proportional to the severity of myocardial damage. In humans cardiac troponin I (cTnI) concentrations are used to assess the risk of complications in patients with myocardial ischemia, myocarditis, arrhythmia, critical illness, cardiac contusion, and congestive heart failure. Measurement of circulating cTnI have been shown to be more sensitive means of detecting myocardial cell injury than measurement of either plasma cardiac troponin T or serum creatine kinase isoenzyme in cats after blunt thoracic injury.

The final value of measuring circulating troponin concentrations in cats with hypertrophic cardiomyopathy (HCM) is not well established. There have been several studies that have proven an increase in circulating troponin levels in HCM cats. Sleeper et al have published normal values for circulating plasma troponin I concentrations in cats. Schober et al found elevated troponin concentrations in cats with cardiomyopathy. Connolly et al showed increase in cTnI cats compared with normal cats and found statistically significant but weak correlation of cTnI serum concentration to the thickness of the left ventricular free wall but not with the interventricular septum on echocardiogram. Overall their assay revealed 87% sensitivity and 84% specificity. Herndon *et al* revealed similar results of increased cTnI levels in HCM cats compared with a normal population. Herndon's also displayed 85% sensitivity and 97 % specificity. These results are somewhat limited by the fact the several of the 'normal' cats had not had an echocardiogram performed. Also this study only studied pre-selected cats with moderate to severe HCM thus the results may be of limited value in cats with mild disease and the positive predictive value may also be limited by the fact the no other populations (ie, cats with concurrent disease or other forms of cardiac disease) were study.

So while the potential for using cardiac troponins may be high there is sill a number of other studies that need to be performed prior to its utilization as a screening tool for cats with HCM. Assessment of cats with other diseases or other forms of cardiac disease may be useful. Also assessing larger populations of consecutive cats will also be useful in helping determine whether this test will be of value as a screening tool.

Natriuretic Peptides

Atrial and brain natriuretic peptides (ANP and BNP, respectively) are small peptides that are released from the heart that counter the negative effects of angiotensin II and sympathetic activation. ANP is a 28 amino acid peptide secreted from the atria in response to atrial stretch. It is secreted as a propeptide that is cleaved into the biologically active 28-amino-acid C-terminal ANP and the 98-amino acid N-terminal (NT)-proANP that are secreted into circulation in equimolar quantities. The N-terminal portion however has a longer half-life in circulation and is more easily measured. BNP on the other hand is secreted primarily from the ventricles (although there is some atrial release of this peptide) due to increases stress on individual myocytes. It is a 32-amino acid peptide that shares structural and biological similarities to ANP. Both ANP and BNP bind to the natriuretic peptide A receptor which mediates natriuresis, vasodilation, renin inhibition, antimitogenesis, and lusitropic effects in the heart. Both peptides are cleared via the natriuretic peptide-C receptor and degraded by neutral endopeptidase.

Circulating levels of ANP and BNP have become known as an important diagnostic test and prognostic marker for congestive heart failure in human cardiac patients. In veterinary medicine small studies have shown increased levels of BNP and ANP along with several other hormones in dogs with congestive heart failure compared with dogs with heart disease and no heart failure. Prosek *et al.* reported increased circulating levels of BNP in dogs with congestive heart failure compared to dogs with respiratory induced dyspnea. Biondo *et al.* reported increased immunohistochemical staining for ANP and BNP in four cats with HCM compared with normal cats. HCM cats showed increased and more diffuse staining pattern for ANP and BNP in the atria and only found BNP in the ventricles of HCM cats compared with normal cats. There have been no studies that describe increased circulating BNP for cats with HCM compared to normal cats that this author could find.

Recently however a new test for screening cats for heart disease was advertised and released to test for NT-pro BNP levels. This test is available through Veterinary Diagnostics Institute and is called the Vetsign Feline Cardio SCREEN NT-proBNP test. The results from a study controlled by the Royal Veterinary College of 80 compared 28 normal cats and 52 abnormal cats. Results of this study show low BNP levels in normal cats and elevated levels in asymptomatic cats with heart disease. However, from the results shown there were only 9 cats in this subgroup and there was some overlap between this group and the normal group. There was a clearly significant difference between the normal group and the cats with symptomatic heart disease (heart failure cats). Caution should be taken when assessing these results and this cardiologist strongly recommend restraint at utilizing this test as a screening test as only 9 cats were utilized in this study and this data to my knowledge has not be published in peer reviewed fashion. Where this test appears to be useful is in distinguishing cardiac-related dyspnea versus other causes. However, delay in obtaining results may make this obsolete in practical use at this time. Currently none of these results could be found in peer-reviewed articles. Again, while the prospects of having such a test is very exciting, caution must be taken in utilizing this test based on the current results given by the company to utilize this test as a tool for screening cats for heart disease. Further studies need to be performed to prove the usefulness of this test in such a manner.

Endothelin

Endothelin (ET-1) is a potent 21 amino acid vasoconstricting peptide produced by the vascular endothelium and the heart. It is converted from a 38-39 amino acid peptide by the action of endothelin converting enzyme (ECE). Elevations in ET-1 in heart failure patients have been reported in people and in dogs. In people these levels have been found to have significant correlations with the degree of functional impairment. Prosek et al reported plasma endothelin immunoreactivity in healthy cats and cats with cardiomyopathy. Plasma ET-1 mean (95% CI) concentrations were 0.777 (0.6536–0.924) fmol/mL in the control cats, 1.427 (0.922–2.209) fmol/mL in 12 asymptomatic cats with cardiomyopathy but and 2.360 (1.666–3.343) fmol/mL in 16 cats with cardiomyopathy (HCM = 8, RCM/UCM = 7, DCM = 1) and CHF (n = 15) or STE (n = 4). Plasma immunoreactivity of ET-1 was significantly higher in asymptomatic cats with myocardial disease versus normal cats and in symptomatic cats with myocardial disease with versus normal cats. Once again small sample size and overlap in the normal and asymptomatic affected cats limits this test's ability to be used a screening tool.

Genetic Testing

Currently in Maine Coon cats with HCM, Meurs et al have identified causative mutations several sarcomeric genes, including the myosin binding protein C (MYBPC3) gene. Reductions in the protein in myocardium from affected cats in comparison to control cats were found by this group. They identified a single base pair change (G to C) in the feline MYBPC3 gene in affected cats that altered the protein conformation of this gene and resulted in sarcomeric disorganization. Currently testing is still currently being performed and evaluation of this test as a screening tool is ongoing. In this authors experience we have found mixed results when comparing genetic testing results with echocardiographic results. Opinions have to be conserved at this time because a single negative echocardiographic result for HCM on cats that test positive for the mutation may not be predictive for future disease in these cats. While these are very exciting and intriguing test one must also realized that this has only been assessed in Maine Coon familial HCM and can not be applied to other cat breeds at current time. This, however, is a huge start in the utilization of DNA technology is assessing this disease in all cats.

SUMMARY

The prospect of being able to screen cats for heart disease utilizing biochemical testing is very exciting. This can be utilized to help guide owners in seeking further more expensive and time consuming testing (ie, echocardiography and specialist evaluation) and in identifying asymptomatic cats who might be at risk for developing congestive heart failure (CHF) if placed under anesthesia or given fluid therapy. Currently the status of such test is questionable at best for use in this manner. Most results suggest that these tests may be best utilized for differentiating cardiac dyspnea from other causes of dyspnea. However, given the methodology of running these test, the limited scope of available labs that run these test and the length of test turnaround, utilization of these test to decide which systems to work up may be obsolete and other test may be more useful given the urgency of need. Further studies need to be performed and test modifications validated for use prior to being able to use these test in an efficient manner. It is feasible given the progress thus far that these goals could be accomplished in the near future and give newer technologies and the advancement of proteomics as a field of interest new more sensitive and specific proteins may be found to be utilized for screening our cardiac patients.

CLINICAL CARDIOLOGY UPDATE: CONGESTIVE HEART FAILURE THERAPY

Henry W. Green, III, DVM, Dipl. ACVIM – Cardiology
School of Veterinary Medicine
Purdue University, West Lafayette, IN

There are many different diseases that can cause signs of congestive heart failure (CHF); thus there are numerous approaches one can take for therapy depending on the patient's particular circumstance(s). There is a heavy reliance on medical management to control clinical signs of heart failure. The ultimate goal of which is to improve the patient's **quality** and potentially length of life generally accomplished by reducing retention of salt and water, improving cardiac function and reducing cardiac workload. Owners must be made aware of this goal as there are very few of curable diseases that cause congestive heart failure.

Specific treatment decisions are made possible by an accurate diagnosis of primary cause of the clinical signs (systolic or diastolic pump failure). Other considerations include, the timing of the clinical signs (acute vs. chronic HF), the severity of disease (mild, moderate, or severe HF), and the predominant manifestation of clinical signs (ie, left vs. right heart failure and congestive vs. low-output failure).

In recent years, there has been a greater understanding and appreciation for the role of neuroendocrine system changes in heart failure. With this understanding came a new focus on therapy, not concentrating specifically on symptomatic relief but attempting to slow or possibly stop the progression of disease. Improvement in clinical signs of disease is simply a consequence of modification of these changes. This approach appears to be of primary importance and therapeutic considerations include how disease states affect activation of these systems. Current therapeutic options are facilitated not only by knowledge of pharmacology, hemodynamic effects of drugs, the nature and prevalence of drug side effects, drug efficacy, and the effects of drugs on quality of life but also how given drugs will alter neuroendocrine function.

These systems include but are not limited to the rennin-angiotensin-aldosterone system (RAAS), sympathetic nervous system (SNS), the natriuretic peptides, and arginine vasopressin (ADH). The RAAS system involves the generation of angiotensin II (ANG II) and aldosterone (ALD) in response to reduced renal perfusion, reduced sodium load to the distal convoluted tubule, and increased sympathetic tone. ANG II and ALD both cause increased sodium and water retention along with inducing significant myocardial and vascular smooth muscle remodeling and fibrosis. These latter effects represent irreversible changes and progression of disease. ANG II is also a potent direct vasoconstrictor which increases afterload. ALD has more of a permissive effect on maintaining vascular smooth muscle tone rather than inducing vasoconstriction. The prognosis for heart failure is inversely proportional to the degree of sympathetic nervous system activity. Increased sympathetic tone causes vasoconstriction, renin release, arginine vasopressin release (a potent vasoconstrictor and water retainer) and has been shown to induce myocardial and vascular smooth muscle remodeling and fibrosis. It has been proven that there is baroreceptor dysfunction in heart failure patients and it is felt that this plays the central role in increased sympathetic tone in these patients. Natriuretic peptides (ANP and BNP) are produced by the atria and ventricles in response to increased stretch induced by volume overload and increased pressure. They antagonize the vasoconstriction and sodium/water retention from other neuroendocrine actions and acts as the body's internal regulator. Unfortunately, it is not very effective as they are broken down rather quickly and their effects are essentially neutralized.

In veterinary medicine, alas there is very little data available to assist us in determining the optimal therapy for our patients with congestive heart failure (CHF). Given the abysmal prognosis associated with CHF, there is a need for better therapies or applications of those we have. To date, only data generated using the ACE inhibitors enalapril and benazepril and the positive inotrope pimobendan have been shown to improve the length and quality of life in the dog. Given the paucity of clinical data in veterinary patients, we have become reliant on data generated in human patients with similar disorders with a view to considering these data for our patients. Thus long-term multi-center trials need to be completed to optimize CHF therapy for veterinary patients.

MEDICAL MANAGEMENT

Diuretics are the most commonly drugs for patients with CHF. These drugs reduce the preload on the heart and thus reduce backward pressure on the venous system. Asymptomatic heart disease is usually not associated with measurable activation of certain neuroendocrine systems; however, these neuroendocrine responses are stimulated following diuretic therapy secondary to the decreased preload induced reduction of cardiac output. Because this stimulation of the neuroendocrine system is assumed to be counterproductive, most cardiologists do not recommend single agent use of furosemide for chronic treatment of heart failure. This does not mean that appropriate diuretics should not be used when congestion develops. The combined use of ACE inhibitors and diuretics compromises one of the kidneys' normal compensatory mechanisms (vasoconstriction of the efferent arteriole) and can lead to azotemia when excessive diuretic dose is initiated. While it is this author's experience that this is not a common occurrence, I strongly recommend assessing renal function if possible prior to onset of this therapy and adjusting therapy accordingly. We currently use the lowest possible dose of furosemide in animals with CHF. This often means a degree of experimentation must be performed to best evaluate an individual animal's needs. In most instances of mild CHF, canine patients are released from our hospital on 1 mg/kg q 12 PO q 12 hrs, and in most cats we initially try to use 6.25 mg/cat/day for chronic therapy. When a dose of 2.2 mg/kg twice to three times a day is exceeded during chronic therapy, a thiazide diuretic (hydrochlorothiazide) is "stacked" on to therapy as an opposed to further increase in furosemide dosing. At this level of dosing some degree of diuretic resistance has been reached the addition of a synergistic diuretic is often of great benefit to your patient. While others suggest utilizing spironolactone in this capacity we typically will not due to the minimal diuresis affects of this drug. Spironolactone has however gained a more constant place in therapy due to the additional benefit of aldosterone-antagonism, and has been shown to have survival benefits in human CHF studies. Thus we often will have spironolactone on board concurrently at the onset of therapy for the CHF patient. The dosing spironolactone to this end point in dogs is highly empirical as no study has been repeated to mimic that seen in humans although in numerous animal models this antifibrotic effect has been duly noted.

Angiotensin-converting enzyme inhibitors (ACE-I) are commonly used in the management of heart failure. Their benefits include reductions in plasma concentrations of angiotensin II and aldosterone; therefore, fluid retention and vasoconstriction are inhibited. ACE inhibition also is known to reduce the progressive cardiac enlargement and remodeling that attends most forms of heart failure.

Enalapril (0.5 mg/kg SID to BID) is the ACE inhibitor most frequently used for dogs in the United States. We standardly employ twice a day dosing for dogs and feel this is most appropriate to achieve benefits for CHF and has been safe in the absence of significant pre-existing renal disease or excessive concurrent diuretic use. Although enalapril is licensed for use only in dogs, its successful use has been described in cats with hypertrophic cardiomyopathy (HCM). Another ACE-I commonly used in the US is benazepril, 0.25–0.5 mg/kg PO q 24–12 hours (dogs) and 1.25 mg PO q 24 hours (cats).

Other direct-acting arteriolar vasodilators such as amlodipine or hydralazine may be very useful as disease progresses. While these drugs lack the favorable neuroendocrine effects that are associated with ACE-I, we often consider use of one of these (preferably amlodipine) patients with CHF resulting from mitral valve disease or those with significant mitral regurgitation secondary to annular dilation especially when standard therapy (discussed below) appear inadequate.

With myocardial failure (dilated cardiomyopathy, end-stage mitral regurgitation), positive inotropes play an integral role. Positive inotropes may also have a beneficial effect in early mitral regurgitation by reducing the severity of regurgitation through reduction in isovolumetric contraction time and geometrical changes on the mitral annulus. Pimobendan is a new cardiac medication which acts as a calcium-sensitizing agent to increase inotropy. Because the drug increases the sensitivity of the contractile elements to the existing calcium, there seem to be fewer deleterious effects than drugs that act by increasing calcium flux into the myocardium. Inhibition of phosphodiesterase also may account for some of the beneficial effects of pimobendan. There has been no documentation of increased mortality in dogs treated with pimobendan and improvements in clinical signs may result in longer survival for dogs as quality of life impacts an owner's decision to euthanize the dog. This will be determined as more study results are released on this drug. The dose of pimobendan for dogs is 0.25 mg/kg q 12 hrs. The dose for cats (those with systolic dysfunction) has been proposed to be 1.25 mg/cat q 12 hours but there is very limited experience with this drug in cats.

The use of digoxin in heart failure has been debated for hundreds of years. It is certainly recognized as a drug with beneficial effects but with a significant risk for toxicity. There is no argument against its use with atrial fibrillation but some controversy still exists about its use with normal sinus rhythm especially in human medicine. The arguments for using digoxin include its positive inotropic effect, as well as restoration of blunted baroreceptor responses and reduction of excessive sympathetic tone which is important in the neuroendocrine based treatment of CHF. In a large trial in people with heart failure, digitalis did not impact mortality, but did reduce the need for hospitalization. Those who are not enthusiastic users of digoxin point out that the drug has significant potential for toxicity, that it can be difficult to dose in veterinary patients, and that it has not been documented to improve survival. This author has not experience such frequent difficulties with toxicities or dosing. We historically employed digoxin as the third wing of triple therapy for CHF however since the FDA approval of pimobendan we employ ACE inhibitors, pimobendan, and diuretics for the early stages of CHF, and add digoxin when significant supraventricular arrhythmias (ie, atrial fibrillation), recurrent syncope, or advancing CHF requires additional therapies.

Beta-blockers (propranolol and atenolol) have been used for many years in cats with HCM. While there benefit in this disease is under fire at the moment, more recently, beta blockade has gained favor in dogs as a therapeutic modality for treatment of heart failure. Many human studies on the use of beta blockers (ie, metoprolol, carvedilol) have documented the benefits of chronic treatment with beta-blockers. These effects are often not seen for several months after initiation of beta blockade. Such benefits include up regulation of previously down regulated beta-receptors, improved cardiac performance (improved stroke volume), and improved survival. Because beta-blockers have negative inotropes and chronotropes effects, it is this author's opinion that they may be best employed in animals that are minimally symptomatic with early/mild heart failure where long-term favorable affects (if present) on mortality and hemodynamics may take place with minimal risk of resultant decompensation of the patient.

Finally, one should not leave out the affects of nutrition for treatment of heart disease. Very interesting data have been revealed to show the affects not only of adding low-salt diets to therapeutic regimes but also fish oils that contain n-3 fatty acids help to reduce to production of cytokines and other inflammatory mediators in both people and dogs.

CONCLUSION

It is currently believe the maladaptive neuroendocrine responses play a very important role in the pathogenesis of heart failure. While traditional treatments such as diuretics remain important, most aspects of current management are directed toward blunting of the body's neuroendocrine responses even through dietary modification.

DIAGNOSIS AND TREATMENT OF SYNCOPE

Henry W. Green, III, DVM
Diplomate ACVIM (Cardiology)
School of Veterinary Medicine
Purdue University, West Lafayette, IN

Syncope is the sudden temporary loss of consciousness that is associated with loss of postural tone as a result of an abrupt decrease in cerebral perfusion or decreased delivery of essential nutrients (ie, glucose) to the brain. The true incidence of syncope is unknown; however, it has been reported to occur in a referral database in 0.15% of dogs and 0.03% of cats. This number may be due to the fact that 1) it is a referral database and 2) that often to both the trained and untrained eye it may be difficult to distinguish syncope from seizure activity.

During a syncopal event, animals will usually collapse into lateral recumbency and may have concurrent stiffening of the limbs, opisthotonous, urination and vocalization. However, it is uncommon to see persistent facial fits, persistent tonic/clonic motion, defecation, postictal dementia, and neurologic deficits with cardiovascular mediated syncope. What may often confuse one who witnesses a syncopal event is that on occasion some animals may have "convulsive syncopal episodes" (CSE) that results from severe hypotension or asystole. Typically CSE are preceded by loss of muscle tone whereas seizure activity is usually preceded by atypical limb or facial movement or even staring spells prior to the loss of body tone.

ETIOLOGY AND PATHOPHYSIOLOGY

The mechanisms underlying syncope are usually rather acute in nature. These mechanisms usually involve reduced cardiac output resulting from arrhythmias or decreased cardiac filling, obstruction of blood flow from the heart, hypoxia or hypoglycemia (with normal cerebral flow) or severe decreased vascular resistance related to neurocardiogenic reflexes. There are numerous diseases that can result in any one or a combination of these mechanisms. A partial list is presented in Table 1.

The vast majority of syncopal events in veterinary medicine are due to a transient reduction in brain blood flow. A sudden decrease in cardiac output (CO) or vascular resistance reduces mean arterial pressure may both result in reduction of cerebral blood flow. The most common causes we see in our patients are cardiogenic in nature. Two thirds of dogs and cats with syncope also have a cardiac disease. Most of these are related to rhythm disturbances which are secondary to inherent cardiac disease. Underlying cardiac functional or structural abnormalities exacerbate the negative effect of arrhythmias on cardiac output. Poor myocardial contractility, impaired filling as with pericardial disease or outflow obstructions can all result in an inability of the heart to maintain sufficient cardiac output to meet increased demand during excitable states, even under normal cardiac rhythms.

Non-cardiogenic diseases such as those that result in increased intracranial pressure can result in syncope also by reducing cerebral perfusion pressure by compressing intracranial vessels. While the majority of animals with severe hypoglycemia will present with weakness or seizures, a fair number may present with syncope or CVE while maintaining normal cardiac output. Hypoxia as a result of right to left shunts, severe acute anemia or pulmonary disease can result in insufficient cerebral oxygen delivery and syncope.

Another common occurrence that we see is cough (tussives) syncope. Some like to use the term 'cough drop' to describe syncope induced in this manner. This form of situational syncope occurs most often in brachycephalic dogs; however, it is also common in dogs with airway disease, tracheal collapse, or those with severe left atrial (LA) enlargement causing compression of the left mainstem bronchus. Coughing results in increased intrathoracic pressure, which decreases venous return (preload) and cardiac output. It also decreases intracranial pressures both of which may cause a decease in cerebral perfusion if severe enough coughing occurs. Coughing may also induce reflexive bradycardia by stimulation of the vagal nerve.

Neurocardiogenic (vasovagal) reflex resulting in syncope is less common in animals than in people however there are reports of syncope that occurs secondary to sudden bradycardia following bouts of tachycardia, especially in small breed dogs with advanced valvular disease. In cases of neurocardiogenic syncope, acute sympathetic activity (induced by excitement) provokes a strong reflex vagal response that results in bradycardia. Ventricular mechanoreceptors play a huge role in this reflex in that their activation due to forceful contraction results in a surge in afferent neural traffic stimulating paradoxical brainstem response to vagal activation.

APPROACH TO THE PATIENT WITH SYNCOPE

Clues as to the underlying cause of the episodes can be elicited through a thorough history and physical examination of the animal. Getting a detailed (almost dramatic) description of the events as they occurred as well as the preceding events, prodromal signs, and the animal's mentation and behavior prior to and after the event can help in differentiating cardiovascular syncope from seizure activity and other causes of collapse. In a nice human prospective study the etiology of the syncopal event was able to be correctly elicited in 32% of patients based on obtaining a thorough history and physical examination. Performing diagnostic testing in a stepwise manner is critical in diagnosing the syncopal patient.

Some questions you should consider asking when obtaining a history include:

- What was the animal doing immediately prior to the event?
- How long did the event last?

- Did the animal lose consciousness during the event?
- Did the animal have muscle (motor activity) movement during the event?
- If not; did the muscles appear stiff or relaxed?
- Did the animal urinate or defecate?
- Was the animal normal after the event or disoriented and confused and if so for how long after.
- Current medications.
- Any possible exposure to toxins?
- Have there been any changes in behavior recently?
- Was there any vomiting or coughing prior to the event?

While this is not an all inclusive list of questions and the answers may take you down different lines of questioning, answers to most of these questions may help you decide to follow the path of seizure or syncope for you next steps in diagnostic testing.

Routine database of CBC, biochemical profile, urinalysis, heartworm test, and arterial blood pressure measurement should be performed. In some cases testing for adrenal and thyroid abnormalities should also be performed. In the syncopal patient, however, these tests are most usually normal; however, it is important to perform them to rule out some non-cardiogenic causes of collapse.

A resting electrocardiogram (ECG) should be obtained and the rhythm should be evaluated for at least 1 minute if not longer and while the animal is calm and it is excited. In dogs with bradycardia ECG should be evaluated a second time following the administration of atropine 0.04 mg/kg IV or SC. Dogs with underlying sinus node disease will show an inadequate response (heart rate increase to <140 bpm). Dogs with vagal tone as the underlying mechanism for bradycardia typically have heart rates that increase above 160 bpm. Normal heart rates on transient baseline ECGs, however, do not completely rule out arrhythmias as the underlying cause of the syncopal episode.

Thoracic radiographs should be performed to evaluate lungs, pleural space, mediastinum, and pulmonary vasculature as well as normal cardiac size and shape. Echocardiogram should be performed even if no murmurs are ausculted on physical examination to assess global cardiac function and to rule out the present of pericardial disease and obstructive cardiac masses.

In the face of finding all of the aforementioned test to be relatively normal (blood work, ECG, radiographs, and echocardiography) the clinician should consider ambulatory ECG monitoring with either Holter or event monitoring. Ambulatory monitoring can help identify or exclude cardiac arrhythmias as a cause for syncope in some animals.

Holter monitoring is 24 to 48 hours of continuous ECG monitoring. It is most likely to be diagnostic of syncopal events in animals with multiple and frequent syncopal episodes. To make a definitive diagnosis a syncopal episode must occur while the animal is being monitored. However, just because frequent events are occurring doesn't increase the likelihood of an event occurring during testing. Holter monitoring does allow one to identify any arrhythmia and quantitate the severity of arrhythmias that might increase the suspicion that the syncopal events are induced by arrhythmias. Because arrhythmias often occur without clinical signs this ability to evaluate the entire recording period is a very useful aspect of Holter monitoring. Holter monitors are also very useful for assessment of anti-arrhythmic therapy efficacy.

Event monitors are typically worn for 1 to 2 weeks periods in our patients that allow longer periods of assessment than with Holter monitoring. The event recording system does need to be activated when an event is observed. The monitor then saves to memory a portion of the recording prior to and after activation. The save recording is then transmitted via telephone to be printed. Event recorders have a higher diagnostic yield than Holter monitors; however, their biggest disadvantage is that they do not save recordings of potentially significant arrhythmias unless activated and they can not quantify the frequency of arrhythmias.

TREATMENT

Therapy of animals with syncope episodes is intended to manage the underlying disease and avoidance of precipitating activities such as excitement as much as one can. In as such treatment of specific causes is sometimes obvious for example correcting anemia or treating respiratory or metabolic disorders.

In the case of heart failure patients: addressing proper management of the patient in heart failure: Institute appropriate therapy with diuretics, angiotensin-converting enzyme inhibitors (ACE-I), and inotropic support if needed. In the case of patients who are already being treated with triple therapy, optimizing drug therapy dosages or stacking additional medications such as additional diuretics or vasodilators may help to place the patient in a more positive hemodynamic state and thus resolving syncopal signs.

If tachyarrhythmias are the apparent cause, treating with the appropriate anti-arrhythmic (or combination of anti-arrhythmic) will reduce or eliminate the number and severity of the arrhythmias such that the signs are eliminated. In the case of those arrhythmias that can not be eliminated such as atrial fibrillation associated with advanced heart disease, than using drug combinations that slows the number of impulses that cross the AV node to the ventricles will appropriately slow the heart rate enough to allow for appropriate ventricular filling and contraction that syncopal signs are eliminated or reduced significantly.

In the case of bradyarrhythmias, than pacemaker therapy may be warranted; especially those cases that don't respond to atropine trials. Other strategies that have been effective, at least anecdotally include using theophylline or aminophylline to attempt to increase heart rate. We have found that often this therapy may be effective early but becomes ineffective as time passes on. We have also successfully employed pacemaker therapy in animals where syncope was apparently induced by coughing and the cause of the cough could not be resolved (ie, severe LA enlargement).

In the rare cases of neurocardiogenic syncope, pacemaker therapy is not likely to alter the hypotension that results. In suspected cases, therapy with beta-blockers can be used to blunt the initiating sympathetically induced tachycardia and the hyperkinetic ventricular contractions that stimulate the mechanoreceptors. The concern with utilizing beta-blocker therapy along is exacerbation of the resultant bradycardia thus these patients should be monitored very closely and combination of drug and pacemaker therapy may be the most appropriate for these animals.

SUMMARY

Syncope can be a very difficult diagnosis and hard to distinguish from seizures or other causes of collapse. An adequate physical examination and understanding of the etiology and pathophysiology along with a stepwise approach to animals presenting with this clinical complaint can expedite uncovering the underlying cause and allow for early intervention for these animals.

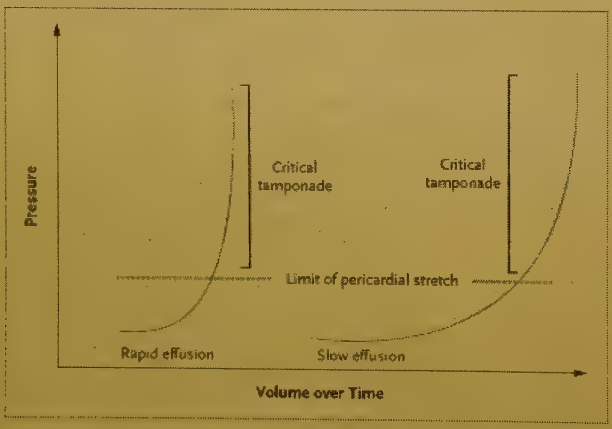
DISEASES OF THE PERICARDIUM

Henry W. Green, III, DVM, Dipl. ACVIM (Cardiology)
School of Veterinary Medicine
Purdue University, West Lafayette, IN

Pericardial diseases are commonly overlooked or mistaken for other cardiac and noncardiac disorders. This is most likely secondary to the fact that pericardial disease represents a relatively small portion of clinically important cardiovascular diseases in dogs and cats and because the physical findings may be relatively indistinct. Paramount to the understanding of clinical presentation, diagnosis and therapy of pericardial disease is the realization of the underlying pathophysiology.

Pericardial disease cause **diastolic cardiac dysfunction** with no to minimal if any alterations in intrinsic systolic function. Elevated intrapericardial pressure inhibits diastolic cardiac filling and as this pressure rises above cardiac diastolic filling pressure, **cardiac tamponade** occurs which can present clinically in either acute or chronic forms. In either case cardiac tamponade results in a significant reduction in preload for any given venous filling pressure. Reducing preload results in decreased cardiac output assuming heart rate, cardiac contractility and vascular resistance is unchanged.

The body's response to the aforementioned decreased cardiac output include increased sympathetic tone and activation of the renin-angiotensin-aldosterone system (RAAS) with resultant increased heart rate, augmented cardiac contractility, sodium and water retention and increased peripheral vascular resistance. The increase plasma volume increases the preload which in combination with the increased heart rate and improved contractility; initially restores cardiac output to near normal. The increased preload, however, is attained at the expense of the elevated venous filling pressures which is eventually manifest as signs of congestion. Because the right heart is more sensitive to pericardial pressure, the signs of right-sided congestive heart failure (jugular venous distention, hepatomegaly, ascites, +/- pleural effusion) predominate.



ETIOLOGY

Congenital

Several congenital diseases of the pericardium are recognized in small animal species. Peritoneopericardial diaphragmatic hernias (PPDH) are the most common type of abnormality encountered. Intrapericardial cysts and partial pericardial defects have been sporadically reported which congenital complete absence of the pericardium is exceedingly rare.

Congenital PPDH occurs as an isolated defect and in association with umbilical hernias, malformed or absent sternebrae, pectus excavatum, and a variety of congenital heart defects. Clinical signs in dogs and cats with PPDH vary in relation to the organs that are displaced into the pericardium and the degree to which the blood supply and function of these organs are compromised. The liver is herniated most frequently, followed by the small intestine, spleen, and stomach. Thus, signs of gastrointestinal disease-vomiting, anorexia, and diarrhea are common in dogs and cats with PPDH. Respiratory abnormalities, varying from coughing or wheezing to severe dyspnea, are the next most frequently observed clinical signs. Only rarely are signs of heart failure and cardiac tamponade observed.

Acquired

Pericardial effusion is the most common cause of pericardial disease in the dog (not so common in cats) and accounts for more than 90% of pericardial disorders, whereas constrictive pericarditis is uncommon by comparison. Clinically significant effusions are most commonly secondary to neoplasia representing 60% to 70% of occurrences with **hemangiosarcomas** or **heart base tumors (chemodectomas or thyroid carcinomas)** occurring most commonly. Neoplastic effusions usually occur in dogs greater than 7 years of age (average 9+ years). German shepherd dogs and Golden retrievers are predisposed to hemangiosarcoma. Brachycephalic breeds (Boxers, Boston terriers) are reportedly predisposed to heart base tumors. Mesothelioma is the most common primary tumor of the pericardium. Idiopathic pericardial effusions comprise about 30% of clinical cases. Most commonly affected are medium to large breed, middle-aged (average age 7 years) male dogs. The German shepherd dog also is over-represented in this disorder. In cats, pericardial effusion is often associated with feline cardiomyopathy, feline infectious peritonitis, and neoplasia (primarily lymphosarcoma).

DIAGNOSIS

Physical Examination

Clinically most animals with pericardial effusion present with a vague history of lethargy, weakness, exercise intolerance, and anorexia. More severely compromised animals will have obvious clinical signs of abdominal distension, respiratory difficulty, or syncope. Rapidly developing effusions such as seen with **atrial tear, traumatic laceration, bleeding neoplasm** cause acute hypotension, weakness, dyspnea, collapse, and, on occasion, sudden death.

On physical exam, heart sounds are usually muffled, and in cases with pleural effusion lung sounds may be diminished as well. Hepatomegaly and free abdominal fluid are common findings unless the effusion is of very sudden onset. Femoral arterial pulses are often weak as a consequence of peripheral vasoconstriction and reduced stroke volume. **Pulsus paradoxus** (inspiratory fall in systemic arterial pressure exceeding 10 mmHg) is a valuable clinical sign that may be seen in cardiac tamponade. When the systemic veins are distended and ventricular filling is limited by cardiac tamponade, inspiration increases venous return to the right side of the heart and further raises intrapericardial pressure, reducing left ventricular dispensibility. The interventricular septum is displaced toward the left ventricle, causing a significant reduction in left ventricular filling, stroke volume, and systemic blood pressure.

Jugular venous distention or a positive hepatojugular reflux is almost invariably present. Measurement of central venous pressure (CVP) is valuable when evaluation of the jugular veins is equivocal. Measures of CVP usually exceed 10-12 mmHg (normal = < 6 mmHg) when cardiac tamponade is present.

Radiography

Thoracic radiography typically demonstrates a markedly enlarged, globoid cardiac silhouette. It some cases evidence of pulmonary underperfusion may be noted where there is significant reductions in cardiac output. Pleural effusion may or may not be present. In cases of peritoneal pericardial diaphragmatic hernia, variable radiographic densities within the cardiac silhouette and sternal abnormalities may be noted.

Electrocardiography

Electrocardiographic abnormalities classically seen with pericardial effusion include low amplitude complex size, electrical alternans (alternating variation in the amplitude of QRS complexes with every other beat), and ST segment elevation or depression. Dampening of the PQRS complexes by the accumulated fluid and diminished cardiac filling are responsible for observed low amplitude complexes. Electrical alternans is caused by the rhythmic swinging of the heart within the fluid filled pericardial sac. Atrial arrhythmias, including atrial fibrillation, are also observed on occasion. Please note the absence of any or all of these findings in no way rules out a diagnosis of pericardial effusion.

Echocardiography

Echocardiography is the most sensitive and specific noninvasive method of detecting pericardial effusion. Echocardiography can detect as little as 15 mL of intrapericardial fluid. An anechoic space between the epicardium and pericardium is the classic echocardiographic finding in pericardial effusion. The heart can often be observed swinging from side to side within the pericardium (demonstrates the cause of electrical alternans). Overall cardiac chamber size is diminished when pericardial effusion causes impaired cardiac filling. The right ventricular free wall (RVFW) often appears hyperechoic due to the dramatic difference in echogenicity between the pericardial effusion and myocardium. This should not be interpreted as an abnormality of the RVFW. Echocardiography often permits visualization of intrapericardiac or cardiac mass lesions. Whenever possible, echocardiography should be performed before pericardiocentesis, as the pericardial fluid will greatly enhance the ability to visualize mass lesions on the heart or pericardium. It is important to realize that small tumors can be easily missed.

THERAPY

Pericardiocentesis

Pericardiocentesis is the treatment of choice for stabilization of dogs and cats with pericardial effusion and cardiac tamponade and is associated with minimal complications. A right-sided approach lessens the chance of coronary artery damage. Surgical preparation of a large area over the right hemithorax is necessary prior to performing pericardiocentesis. Local anesthesia is usually adequate however mild sedation is sometimes necessary.

Thoracic radiographs can be helpful in determining the optimal puncture site however most times this can be performed between the fourth to sixth rib spaces at the costocondral junction. The size of the needle or catheter used is dependent on the size of the animal. In cats a 19- or 21-gauge butterfly catheter may be adequate while in large dogs a 16-gauge over-the-needle catheter may be needed. The needle or catheter should be attached to a three-way stopcock, extension tubing, and a syringe, to allow constant negative pressure to be applied during insertion and drainage. Care should be taken to avoid the large vessels that run along the caudal border of the ribs. Once the catheter has been inserted through the skin, negative pressure should be applied. While monitoring the ECG, the catheter is advanced toward the heart. If pleural effusion is present, it will be obtained immediately upon entering the thoracic cavity. It is most commonly a clear to pale yellow color. As the catheter is advanced and contacts the pericardium, a scratching sensation will be noticed. Minimal advancement will result in penetration of the pericardium. Most pericardial effusions are hemorrhagic and have a "port wine" appearance. Once effusion of this character is obtained, the catheter should be advanced over the needle, and the needle removed. The remainder of the fluid should then be drained using the catheter. Advancing the needle too far will result in contact with the epicardium. This is often felt as a tapping or more intense scratching sensation and commonly results in ventricular arrhythmias. These arrhythmias are usually self-limiting following retraction of the needle or catheter.

Aspirated fluid should be compared with peripheral blood (PCV, protein, xanthochromia, clotting) and the pericardial sac subsequently drained. Pericardial effusion can be differentiated from peripheral blood in that it rarely clots unless it is from very recent hemorrhage. Routine cytology and fluid analysis are prudently obtained to exclude bacterial, fungal, or obvious neoplastic etiologies. Culture and sensitivity is performed only is cytology indicates a need for this test. It is usually **not** possible to distinguish the most common neoplastic effusates (hemangiosarcoma, heart base tumors) from idiopathic effusions on the basis of red cell or white cell counts, protein content, or by cytologic examination. Nor is the pH of the fluid a reliable indicator of the etiology of the effusion.

With idiopathic hemorrhagic pericardial effusion, pericardiocentesis is curative in approximately 50% of the cases. In the remainder, repeat centesis is necessary to control clinical signs. Fluid may reaccumulate rapidly or may not recur for years. In those requiring more than two centeses, we recommend performing subtotal pericardiectomy or periocardiotomy. With aortic body tumors subtotal pericardiectomy or pericardiotomy may afford palliation for up three years as these tumors are slow to grow and metastasize. Hemangiosarcoma of the right atrium is associated with a poor long-term prognosis. Most mass lesions involving the right atrium or right ventricle are not amenable to surgical removal. Those involving the right auricular appendage may be removed by auriculectomy; however, is still associated with poor prognosis.

Newer techniques such as thorascopic pericardiectomy and percutaneous pericardial balloon dilation may be reasonable alternatives to subtotal pericardiectomy in both neoplastic and benign effusions. This may provide significant palliation for patients with pericardial effusion and the resultant cardiac tamponade without necessitating a thoracotomy. These techniques allow the pericardial fluid to drain into the pleural space to be reabsorbed. Thorascopic procedures may have the advantage of being able to obtain samples of pericardium for histopathology over ballooning techniques however the procedure remains more costly than ballooning procedures.

Prognosis

The prognosis is good for patients with idiopathic effusions or effusions due to pericardial cysts or peritoneopericardial hernias. The prognosis for dogs with hemangiosarcoma is poor even with aggressive surgical and medical therapy. The prospects for animals with heart base tumors are more variable. Many dogs with slow growing chemodectomas experience long survival times with good quality of life for a year or more following subtotal pericardiectomy.

DIAGNOSIS AND MANAGEMENT OF SYNCOPE

N. Sydney Moïse, DVM, Diplomate ACVIM
College of Veterinary Medicine
Cornell University, Ithaca, NY

Syncope is the loss of consciousness due to inadequate perfusion to the brain. Although some points from the description of a 'collapse' can differentiate true syncope from a seizure, it is not always possible to do so. Always the many causes of syncope and seizures should be consider in the early phase of making the diagnosis. The cardiovascular causes of syncope can be categorized into those which are (1) due to cardiac arrhythmias (severe tachycardias or profound bradycardia), (2) obstruction to output (subaortic stenosis, tumor obstruction, (3) poor systolic function (dilated cardiomyopathy), (4) restriction to cardiac filling (cardiac tamponade), (5) systemic hypotension or (5) severe hypoxia (right to left shunt such as tetralogy of Fallot).

What are the diagnostics that are done in the evaluation of weakness and collapse? Radiography will reveal evidence of pulmonary pathology and usually give an appreciation of cardiac size. Electrocardiography may provide the evidence for the diagnosis of the rhythm disorder, although 24-hour ambulatory (Holter) monitoring, event recorders, or implantable recording devices may be required. Echocardiography will give the structure and functional characteristics to determine the specific disease. Finally, blood pressure and laboratory tests will clear the animal of other diseases and provide the foundation to know that drug therapy is not contraindicated if underlying organ dysfunction is severe.

What are the rhythm abnormalities that can result in weakness or collapse? When the heart rate is too slow or too fast, weakness can occur. The degree of these extremes dictates the severity of the clinical signs. The parameters include both the rate and the duration of the extreme in rate. Critical to this factor is the generation of the systemic blood pressure. For example a heart rate of greater than 260 bpm is more devastating than a rate of 200 bpm, but if the faster rate persist for only a few seconds and the latter for hours the bad consequences are greater. This same thought follows through with the length and rate of bradycardias. When the extreme rates cause a loss of cerebral blood flow (inadequate pressure) for more than 8 seconds, then collapse or syncope will result. The most common tachycardias that can cause weakness include atrial fibrillation, atrial tachycardia, and ventricular tachycardia. The most common bradycardias include third-degree heart block, advanced second-degree heart block, and sick sinus syndrome. It is also possible for syncope to be neurogenically mediated (eg, associated with postural changes, coughing, urination) whereby a mismatch of heart rate and blood pressure result in inadequate cerebral perfusion.

TREATING ATRIAL FIBRILLATION

The following drugs are ones that can be used to control heart rate by slowing AV nodal conduction.

1. **Digoxin alone**. 0.003 to 0.005 mg/kg BID, lean body weight, frequently reduce this calculated dose by 25% for extra safety, titrate to safe serum level of approximately 0.7 to 1.0 ng/mL. This is lower than past recommendations. *or*
2. **Diltiazem (extended release) alone.** 2 to 4 mg/kg twice daily. Some dogs require higher doses, particularly Great Danes (usual Great Dane requires 240 mg BID), In dogs with very poor systolic function use the lower end of dose range to start; however, a surprising number tolerate and need the highest dose.
3. **Combination of digoxin and diltiazem** dose of either or both may be reduced when used in combination. This combination is most successful when heart failure exists because more sympathetic influence pushes the ventricular response rate higher, thus, the combination is most effective than any drug alone. Watch for excessive slowing of ventricular rate or excessively long pauses (eg, > 3 sec).

In a dog with acute heart failure due to dilated cardiomyopathy and marked tachycardia due to atrial fibrillation the goals must be prioritized. Most of the time severe dyspnea is present in addition to the tachycardia of the atrial fibrillation. The dog must breath before all else. Aggressive, short-term treatment with diuretics is given with acute treatment with nitroglycerin, and some may use nitroprusside with continuous monitoring. The dilemma is whether to treat the dog with dobutamine (improve output) or diltiazem (control heart rate response). A second dilemma concerns the route of drug administration. In the dog that is in complete distress the intravenous route is obvious, but not all dogs are in this most dire position. Some could be treated orally. Response to oral diltiazem can be rapid; however, if there is a negative response the effects can be more protracted if the long-acting preparations are used such as Dilacor®. The effects of regular diltiazem do not last long in the dog and require frequent administration; however, this can be an advantage in a dog where the IV route is not selected, but the long acting medication is not desirable as yet. The unfortunate problem is that with calcium channel blockers and beta-adrenergic blockers the heart rate control comes with the price of hypotension in many dogs with myocardial failure. This is why a combination of treatment with digoxin can be advantageous, but the dog must live long enough to have all the medications achieve adequate blood levels. Once this is achieved, titrating to the oral doses can begin.

TREATING VENTRICULAR TACHYCARDIA

One of the common ventricular tachycardic rhythms that causes syncope occurs in the boxer with arrhythmogenic right ventricular cardiomyopathy. The ventricular tachycardia can be as rapid as 300 bpm resulting in severe hypotension. A plan that can be used to treat such dogs is shown in Table 1.

TREATING BRADYCARDIAS THAT ARE PERMANENT (NOT DRUG-INDUCED)

In dogs with bradycardias as the cause of the syncope, pacemaker implantation is the ideal therapy. This is now a common procedure in the dog and is for the most part successful.

TREATING OBSTRUCTION TO OUTPUT

Some dogs with subaortic stenosis and obstruction to output particularly during exercise may benefit from titration of beta-adrenergic blockade. Only through a clinical trial of such treatment can it be determined in a specific dog that they will in fact improve. On occasion a dog treated with a beta-adrenergic blocker and subaortic stenosis collapses more often and the treatment is discontinued. Some dogs that have heart base tumors (chemodectomas) will collapse; however, it is not known if this collapse is due to obstruction or to some type of neuromediated imbalance from the neoplasia.

RESTRICTION TO FILLING DUE TO CARDIAC TAMPONADE

Pericardiocentesis is required as an emergency procedure. The next major issue to resolve is cause: neoplasia or not. Most of the time echocardiography provides this answer. The most common neoplasias include hemangiosarcoma, chemodectoma, thyroid carcinoma, and lymphosarcoma. Some dogs with pericardial effusion have idiopathic pericarditis and can be treated with pericardectomy.

Table 1. Management of Syncope

Timing of Exam After Diagnosis	Tests	Purpose of Tests	Interpretation of Tests
Initial	Physical examination, blood chemistry, ECG, thoracic radiographs, echocardiography, Holter monitoring	Vital to establish baseline arrhythmia frequency. To determine myocardial function and cardiac size	Judgment of drug efficacy cannot be determined without baseline data. Holter monitoring is required for accuracy
1 to 2 weeks	Recheck Holter after beginning drug. Treatment is most often sotalol at 2 to 3 mg/kg twice daily	To evaluate if an adequate reduction in arrhythmias has occurred and to assess for other ECG drug effects	If inadequate response then the dose is increased. Most average to large boxers require 80 mg twice daily
3 to 4 weeks	Recheck Holter if drug dose was changed at week 1 or 2	To see if dose change decreased the arrhythmia counts	Establish longer-term dose
3 months (optional)	Recheck Holter	To assure antiarrhythmic effect	Change dose if needed and assess dog's response to therapy
6 months	Recheck Holter and echocardiogram	To assure antiarrhythmic effect and to determine if myocardial function remains stable	Add medication is myocardial function is decreasing
12 months	Recheck Holter and echocardiogram	To assure antiarrhythmic effect and to determine if myocardial function remains stable	If antiarrhythmic effect holds and myocardial function is normal then check Holter every 6 months. An abbreviated echocardiogram can be done to track function

FELINE THROMBOEMBOLISM

N. Sydney Moïse, DVM, Diplomate ACVIM,
College of Veterinary Medicine
Cornell University, Ithaca, NY

In this review of thromboembolism in the cat, the short- and long-term therapeutic management will be discussed. Although the focus herein is on treatment of thromboembolization, it is imperative that the following major points be remembered: (1) Almost all cats with thromboembolism have important underlying cardiac disease; (2) Approximately half of the cats with thromboembolism have concurrent clinical signs of congestive heart failure and these need to be considered in the prognosis and treatment; (3) Treatment of thromboembolism in the acute phase can be very challenging if reperfusion injury occurs with survival in part dependent on meticulous monitoring and careful treatment; (4) Long-term treatment to decrease the reoccurrence of thromboembolism is controversial as to the drug choice and dose; and (5) Despite the challenges of thromboembolism (eg, likelihood of severe heart disease, difficulties in treating the acute consequences, expense of treatment, and unknowns regarding the correct long-term treatment for both the cardiac and thromboembolic disease), enough cats survive for an 'adequate' amount of time that the rendered care is deemed worthy by many owners even when they understand the problems.

THE CAUSE OF THE CLINICAL PRESENTATION

Thromboembolism occurs most commonly as the result of cardiac disease in the cat with a clot lodged in the distal aorta and iliac arteries. The arterial occlusion alone is not the cause of the reduced circulation, but the effects of the thrombus cause a cascade of vasoconstriction events that reduce collateral circulation. In order to reproduce the clinical disease experimentally, arterial ligation with the injection of bovine thrombin is required. Thus, it is not primary channel blockade that causes the ischemic neuromyopathy. The cat has many collateral vessels to call upon from the vertebral arterial system, but when this fails to happen the clinical syndrome ensues. Additionally, it is the reopening of these collateral vessels in the 12 to 24 hours after the thromboembolic event that result in the reperfusion injury that kills many cats.

CLINICAL SIGNS OF THROMBOEMBOLISM

Thromboembolism may be the first clinical sign of cardiomyopathy in many cats. Clinical signs include both the direct consequences of thromboembolism and the associated cardiac disease: acute rear limb paralysis, pain, depression, or dyspnea. The majority of cats have both rear limbs affected, although a single limb (rear or front) can be embolized. Occasionally, a cat may have paresis, rather than paralysis (paraplegia) if affected to a lesser degree. The physical examination of cats with aortic thromboembolism might include (1) the absence of femoral pulses, (2) firm to hard cranial tibial and gastrocnemius muscles, (3) pale to black cold foot pads, (4) absence of deep pain response, (5) absence of limb motion below the upper thigh, (6) hypothermia, (7) lack of anal tone and distended bladder, (8) abdominal pain if the mesenteric artery also has been embolized, (9) tachypnea and tachycardia (seen with cardiovascular compromise, stress and pain), (10) bradycardia or irregular cardiac rhythm, (11) heart murmur or gallop sound, or (12) varying degrees of depression.

As with most diseases, the severity of the disease and the resulting clinical presentation are variable. Clinical signs that indicate a 'better' prognosis include pad color that is pale pink, tail movement, good anal tone, upper thigh muscle control, normal mental acuity, eupneic, and normal body temperature. Also, cats have a better prognosis if they have hypertrophic cardiomyopathy and not restrictive cardiomyopathy. In addition, left atrial size affects prognosis with severe dilation being more ominous indicator. The prognosis is worse if congestive heart failure is present.

THE DIAGNOSTIC PLAN

The diagnostic evaluation of the cat with thromboembolism includes blood pressure, echocardiography, thoracic radiography, serum chemistry, and electrocardiography. Although the blood pressure determination in the hind limbs will not be accurate, an assessment from the forelimbs is important to gauge the overall status of the cat. Echocardiography will reveal the type of cardiomyopathy, the severity of the hypertrophy and/or fibrosis, systolic and diastolic dysfunction, size of the atria, presence of pleural effusion, and presence intra-atrial blood stasis or clots. Thoracic radiography permits the determination of pulmonary edema or pleural effusion. Pulmonary edema can exist even if not suspected from the auscultation of the lungs. Moreover, tachypnea is seen in the majority of these cats. The cause can be either pulmonary edema, pain, or both. The radiograph helps to determine if treatment for fluid retention is required.

SERUM CHEMISTRY ABNORMALITIES ARE COMMON AND EXTENSIVE

Azotemia, hyperglycemia, elevation in muscle enzymes (creatine phosphokinase, aspartate aminotransferase and alanine aminotransferase), hyperkalemia, acidosis, hyperphosphatemia, and hypocalcemia can be documented. Azotemia is usually due to poor perfusion to the kidneys and it is this same mechanism that explains the hyperphosphotemia. Hyperglycemia is hypothesized to be due to two factors: stress and increased lactate. Stress causes an increase in adrenergic hormones that inhibits insulin secretion and this in turn causes the increase in blood glucose. Also contributing to the stress response are high glucagon and cortisol levels. Concomitant with this is that lactate levels are high due to muscle anaerobic glycolysis. Lactate is a major gluconeogenic precursor to cause hyperglycemia. It is believed that insulin resistance is likely not responsible for the hyperglycemia in cats. Elevation in muscle enzymes particularly that of creatine phosphokinase, can be dramatic in cats with thromboembolism due to the muscle necrosis. Poor renal perfusion accounts for the hyperphosphatemia, but again the death of muscle serves as a source for massive quantities of phosphorus. The excessive phosphorus binds to calcium and this accounts for the hypocalcemia. Metabolic acidosis develops in response to the lactic acidosis reaching levels that demand specific treatment. All of these biochemical alterations change over time after the thromboembolic event. The ideal situation is for them to return to normal; however, it is important to particularly watch the potassium concentration as it can increase as reperfusion develops.

Electrocardiography is vital on admission not only for the evaluation of the rhythm, but to ascertain the electrocardiographic evidence of the potassium concentration. Frequently, the ECG on admission is normal, but once reperfusion begins (as early as 6 hours after thromboembolism) the potassium concentrations can elevate quickly. Monitoring of the ECG provides a means to monitor the serum potassium level. Attention should be paid to the P wave, S wave and T wave. Most frequently cats will develop S waves, the P wave flattens and the T wave flips to positive as an indicator that the potassium is increasing. It is vital that the serum potassium be rechecked so that treatment can be started early enough to be of benefit. Severe abnormalities in conduction and rhythm progress as the potassium levels increase.

OVERVIEW OF TREATMENT

Treatment of thromboembolism is a matter of multitasking, changing problems, and shifting goals. It is important to realize that the specific treatment is dictated by the amount of time that elapses after thromboembolism. The discussion of treatment will be divided into four stages:

1. Immediate treatment (0 to 6 hours post-thromboembolism);
2. Reperfusion treatment (6 to 18 hours post-thromboembolism);
3. Early recovery from thromboembolism (18 hours to 7 days post-thromboembolism);
4. Long-term management (home care).

IMMEDIATE TREATMENT

The initial problems that coexist with thromboembolism are referable to cardiomyopathy and include (1) respiratory distress because of pulmonary edema and (2) cardiovascular shock. Pain and anxiety occur because of the thromboembolism. Tachypnea and dyspnea are frequently present and the reason for these signs may not be clear without thoracic radiography to determine the presence or not of coexisting pulmonary edema. In the ideal situation the thrombus would be removed within 4 hours, but this is not likely to happen because the availability of the procedure is uncommon and it is unknown if cats can survive such surgery. Also, it would be ideal if the clot could be treated immediately with a clot 'buster' [eg, tissue plasminogen activating factor (TPA)] early such that the amount of cell death is decreased to diminish the problems of reperfusion injury. Again, the proper method, drug, and talent to offer this treatment is currently lacking in veterinary medicine.

IMMEDIATE ANTICOAGULANT TREATMENT

For years, the use of heparin in acute thromboembosis has been purported in the acute situation. We need to all consider the evidence for this treatment and its value. We actually do not have any evidence of its effectiveness in improving the state of these cats. Heparin (unfractionated heparin) is a heterogeneous combination of heparin molecules with disaccharide units of varying lengths. The length of the molecule affects the action. The different size heparin molecules bind in different ways and affect the coagulation in varying degrees. Also, unfractionated heparin has a high affinity to binding with serum protein and cells. Once these are loaded the heparin binds to thrombin (Factor IIa) and form a thrombin-antithrombin-complex that is irreversible. Unfractionated heparin inhibits both Factor Xa and Factor IIa. Inhibition of Factor IIa requires the long sugar residues found in unfractionated heparin and these are not found in the low molecular weight heparins (LMWH). After treatment with heparin, it is possible because of the purported decrease in antithrombin III, that there is a hypercoagulable period, but we do not know if such a time actually exists in cats. The unfractionated heparin dose in the cat is 100 IU/kg given subcutaneously and repeated at 6 hour intervals after a loading dose of. The efficacy has not been evaluated.

Recently LMWH have been professed as better than unfractionated heparin. These heparins are more uniform in their size with fragments of 4 to 8 kD with an average chain length of 15 subunits and 80% < 40 subunits, this is in contrast to the heterogenous mixture of 10 to 100 subunits for the unfractionated heparin. The LMWH are short and bind primarily to Factor Xa and not to Factor IIa. It is may be that this type of inhibition is adequate for preventing clot formation. The LMWH do not require the loading dose that unfractionated heparin requires. Monitoring of LMWH effect is done by measuring Factor Xa activity. Two LMWHs are enoxaparin (Lovenox) and dalteparin (Fragmin). These formulations are approximately 4 times as expensive as unfractionated heparin. The dose of enoxaparin has been 1 to 1.5 mg/kg subcutaneously. The dose of dalteparin used in cats has been approximately 100 IU/kg given subcutaneously every 12 hours has been given to cats. Early studies suggest the half-life of LMWH is short in the cat and that dosing must be more frequent. Although this is not problematic for the hospitalized cat, it is a dilemma if treatment is to be administered at home. Few owners would be able to inject a cat three times per day. The validity of these drugs and the proper dosage in the acute situation of thromboembolism in the cat have not been studied.

IMMEDIATE CONTROL OF CONGESTIVE HEART FAILURE

When pulmonary edema is present diuresis is required with parental administration of furosemide. The dose is important and must be adjusted to the patient and the response. Usually a dose of 1 mg/kg given intravenously is given when the cat has pulmonary edema, but is not in a critical situation when more aggressive treatment is used. The response is assessed and additional doses given as needed. In some cats it may be important to also treat with nitroglycerin ointment with blood pressure monitoring. This treatment is in conjunction with the assessment of hyperkalemia, renal perfusion and importantly cardiovascular shock. Each of these three problems demand fluid therapy, but for a cat with a compromised cardiac status and pulmonary edema, fluids can be catastrophic. However, it is the truth that in such cases the cat may be receiving fluids at half-maintenance level while also getting furosemide. Constant monitoring of mental acuity, blood pressure, heart rate and respiratory rate assist in making the needed adjustments in this 'contradictory regimen of therapy'. The dose of furosemide in cats with critical pulmonary edema and thromboembolism may require repeating every 2 to 4 hours until a response of improvement are seen. When cardiogenic shock is present intravenous infusion with dobutamine may be required in this difficult situation.

It is in the first few hours that control of pain and anxiety are considered somewhat important. Pain and anxiety increase the sympathetic tone and this is very detrimental to cats with cardiomyopathy. Consequently, treatment with medication that would relieve these symptoms is ideal so long as the price is not excessive sedation and hypotension. In the past, acepromazine has been recommended for such treatment; however, this drug is not recommended. Today butorphanol at 0.2 to 0.4 mg/kg subcutaneously every 4 hours or hydromorphone at 0.05 to 0.1 mg/kg subcutaneously are most frequently used. Butorphanol will not give as much analgesia as the hydromorphone, but the latter is more likely to cause dysphoria. Over-sedation can compromise the ability to judge the status of cardiovascular shock and mentation. Other medications such as fentanyl patches are not recommended because they take too long be effective. This is an important consideration because pain in cats with thromboembolism last a relatively short time of less than 6 to 10 hours.

REPERFUSION INJURY

Cats will suffer from reperfusion injury to varying degrees depending on the vascular hyperpermeability, hyperkalemia, edema and acidosis present. In some, there will be no apparent consequences while in others this is the cause of death. The problems to battle in this stage of treatment are hyperkalemia, acidosis, azotemia, cardiac rhythm and conduction problems, shock, and compromised cardiac function. Pulmonary edema must continue to be treated as demanded in cats that suffer from this in addition to the thromboembolism. The clinical signs of reperfusion include depression, arrhythmias, conduction disturbances, and in general, 'crashing.' ECG monitoring permits notification of changes in serum potassium levels. Additionally, monitoring of the serum potassium levels every 2 to 4 hours may be required when possible. Knowing when the potassium concentration is increasing and acting on this situation early is key to success. Acidosis will develop in these cats and contribute to the hyperkalemia. The aggressiveness in the treatment of hyperkalemia depends on its severity. Treatment can include modest fluid therapy with NaCl (careful to watch for pulmonary edema), intravenous glucose (but if the cat is already hyperglycemic this is not effective), sodium bicarbonate (effective for the acidosis too), very low doses of insulin (give with glucose and monitor), to intravenous calcium (directly counteracts the cellular effects of hyperkalemia). Always during the selected treatment the potassium concentration is monitored for effectiveness of treatment and to be alerted to the time to stop treatment. This is important because overshooting treatment past the reperfusion period will result in hypokalemia. Frequently, specific treatment for the heart disease such as ACE inhibitors is not given at this point in the treatment of these cats. Azotemia can be mild to severe depending on the cardiac status, underlying renal reserve, renal perfusion, presence of renal emboli, severity of reperfusion, doses of furosemide required to control pulmonary edema, and fluid administration tolerated to assist during reperfusion. Monitoring blood pressure, heart rate, respiratory rate, mentation, and renal perfusion continue to be important. Pain relief at this stage of the disorder usually is not required.

EARLY RECOVERY FROM THROMBOEMBOLISM

Near the end of the reperfusion period the limbs can swell, sometimes dramatically. The skin can become erythematous and pitting edema can develop. Cats can loose the hair over the limbs. If a cat survives the reperfusion injury it is critical that the entire cat be reevaluated because the furosemide dose, quantity of fluids, specific treatment for hyperkalemia, and pain treatment all will need to be adjusted or eliminated. This is also the time that the monitoring of the physical state of the cat must not stop. Immediately after the intensity of treating a cat with severe reperfusion injury, a false sense of victory can occur and deterioration of the cat can be missed unless vigilance continues. This is especially true for decompensation of the heart and the acute development of pulmonary edema. During this time additional medications that are given orally for the heart can be started and these include ACE inhibitors, aspirin, and potentially clopidogrel. If the cat begins to eat at this time, this is a good prognostic indicator.

LONG-TERM MANAGEMENT

The problems to address in the long-term include treating the (1) underlying cardiac disease and managing congestive heart failure if present, (2) preventing reembolization, and (3) providing the needed care and management for recovery of the limbs form the thromboembolic event.

There remains controversy as to the correct treatment of cats with hypertrophic and restrictive cardiomyopathy. In general, cats that have had an episode of pulmonary edema are treated with angiotensin-converting enzyme (ACE) inhibitors, furosemide at a dose that prevents pulmonary edema and yet preserves renal perfusion. In cats that have not had an episode of pulmonary edema the use of beta-adrenegic blockers or calcium channel blockers is unclear. Given that the majority of cats that leave the hospital after thromboembolism die of congestive heart failure determination of the best treatment of the underlying heart disease is a paramount goal.

It is clear that these cats need treatment to prevent re-embolization which occurs at the rate of about 25% as reported in the most recent reports, but what is uncertain is how this is accomplished. For many decades some have suggested the use of aspirin, while others say it does no good. Studies in the early 1970s showed that experimentally cats treated with aspirin, if thromboembolism did occur, had less severe clinical signs and recovered quicker. But still, thromboembolism occurs. In humans aspirin alone is frequently inadequate to control thromboembolism, whereas, anticoagulation treatment decreases the recurrence. However, treatment with anticoagulants such as coumadin requires rigorous monitoring that is rarely possible in cats. The LMWH could be an alternative, although when these have been used thromboembolism still developed and the target levels were never obtained at the dose used and the half-life appears short. The latter is problematic because the drug must be administered parenterally and it appears that twice daily administration is inadequate. This type of treatment is likely not practical. Recently, an alternative treatment has been suggested which is antiplatelet rather than anticoagulation. This involves the combination of aspirin with another drug that works by a different mechanism to inhibit platelet aggregation. This drug is clopidogrel (Plavex) and recent studies have shown this to be a safe drug in cats.

The mediators of platelet activation include thrombin, ADP, collagen, and thromboxane A_2. Thrombin stimulates platelets to release ADP and thromboxane A_2. Collagen activates platelets to recruit other platelets. The antithrombotic effect of aspirin occurs by irreversibly acetylating cyclo-oxygenase to block formation of thromboxane, but it has no effect on platelet activation by thrombin and ADP. Clopidogrel which is a thienopyridine ADP receptor antagonist exerts its effect of inhibiting platelet aggregation through irreversible inhibition of ADP receptors on the platelet membrane blocks and indirectly reduces binding of fibrinogen and von Willebrand factor. It is the active metabolite (produced through hepatic metabolism) that is the active form of the drug. Clopidogrel also inhibits glycoprotein IIb/IIIa receptor complex and reduces serotonin release from platelets.

Only time will tell which cats will regenerate enough nerve with adequate muscle mass to restore ambulatory function. The amazing fact is, many cats can do this. Disappointingly, before the time has elapsed for these regenerative processes some cats may actually survive the ischemia and reperfusion only to have a leg that never recovers adequate perfusion for regeneration. Such a situation results in euthanasia or amputation of the limb. Some cats may require perfusion studies to determine the status that guides treatment. During the recovery of the limbs the act of dragging the limbs and the sensation return can cause problems. Necrosis, infection and self-mutilation can occur and undermine the success of saving the cat from the critical insult. Bandaging to protect the lower leg from abrasion when the cat drags its legs must be done with care because of the reduced circulation. If skin erosions develop aggressive treatment with cleansing, silver sulfadiazene ointment, and bandaging protection are required. The most common infection of such sores is *Pseudomonas aeruginosa*, similar to burn injuries. Immediate attention is required if a fever develops and an elevation in the white blood cell count. When this type of lesion develops the limb may not be salvaged and amputation is required. Although this is a desperate measure, it is surprising how cats can survive the surgery and live with the single hindlimb.

In summary, the treatment of thromboembolism in the cat entails multitasking and attention to detail. An understanding of the pathophysiology will guide us in designing studies to answer the clinical questions. We have made progress in the treatment of this disease, but there is still a long way to go. The fortunate situation is that there are cats that can survive despite our limited knowledge.

HOW TO TREAT ARRHYTHMIAS IN THE FACE OF HEART FAILURE

N. Sydney Moïse, DVM, MS, Diplomate ACVIM,
College of Veterinary Medicine
Cornell University, Ithaca, NY

MANAGEMENT OF ATRIAL FIBRILLATION WITH HEART FAILURE (NON-EMERGENCY)

Atrial fibrillation in dogs with heart failure is most common in large breed dogs [Dobermans with dilated cardiomyopathy (DCM), Boxers with arrhythmogenic right ventricular cardiomyopathy (ARVC)], giant breed dogs (Great Danes and Newfoundlands with DCM), dogs with degenerative valve disease (usually small dogs), occasional dog with severe left to right shunting and a patent ductus arteriosus. The most common clinical signs include dyspnea, coughing, weakness, weight loss, anorexia, exercise intolerance, and syncope. Ideally a complete physical examination, chemistry panel, blood pressure, thoracic radiograph, echocardiogram, electrocardiogram, and baseline 24-hour Holter monitoring are performed. The 24-hour Holter should be evaluated for the following:

1. Average heart rate, maximum and minimum heart rate
2. Length of time with rate greater than 120 b/m, length of time with rate less than 50 b/m
3. Number and length of pauses
4. Presence of any ventricular arrhythmias
5. Time of day or sleep/wake heart rate trend

TREATMENT CHOICES

The following drugs are ones that can be used to control heart rate by slowing AV nodal conduction.

- **Digoxin alone.** 0.003 to 0.005 mg/kg BID, lean body weight, frequently reduce this calculated dose by 25% for extra safety, titrate to safe serum level less than 1.5 ng/mL, aim for 0.7 to 1.0 ng/mL. This is lower than past recommendations. *or*
- **Diltiazem (extended release) alone.** 2 to 4 mg/kg twice daily. Some dogs require higher doses, particularly Great Danes (usual Great Dane requires 240 mg BID), In the dogs with very poor systolic function use the lower end of dose range to start; however, a surprising number tolerate and need the highest dose.
- **Combination of digoxin and diltiazem.** The dose of either or both may be reduced when used in combination. This combination is most successful when heart failure exists because more sympathetic influence pushes the ventricular response rate higher, thus, the combination is most effective than any drug alone. Watch for excessive slowing of ventricular rate or excessively long pauses (eg, > 3 sec).

The following are drugs used in the treatment of congestive failure (*indicates most commonly used treatment, **indicates frequently added to *commonly used treatment, ***indicates under investigation to add to * commonly used treatment):

- Modest sodium restriction, high protein diet (eggs), B vitamins, antioxidants
- *Furosemide 1 to 4 mg/kg once to three times daily
- **Spironolactone 1 to 2 mg/kg twice daily (usually given with furosemide and ACE inhibitor. Also used with digoxin)
- *ACE inhibitor (enalapril 0.5 mg/kg BID, benazapril 0.5 mg/kg BID, lisinopril 0.5 mg/kg or others)
- **Digoxin 0.003 to 0.005 mg/kg twice daily as maximum dose based on lean weight, reduce dose by 25% for extra safety
- **Pimobendan 0.3 to 0.6 mg/kg/day (data indicates good results for DCM, firm conclusions in dogs with degenerative valve disease pending)
- ***Carvedilol 1 to 1.5 mg/kg twice daily (work-up to this dose slowly) once overt failure is controlled (atenolol or metaprolol may be of value) once stable?

TREATMENT GOALS

An important goal is to control heart failure which will then control signs of failure and to decrease the ventricular response rate (heart rate). The latter is linked to the degree of sympathetic drive and this is greater with overt congestive heart failure (including signs of dyspnea). The desired slowing of the heart rate to a target range must be decided upon. This range is determined by breed, size and disease (rate may need to be higher than that for lone atrial fibrillation). For example a target heart rate goal would be a range between 90 and 120 bpm. Some dogs may need a target range that is 100 to 150 bpm but studies to know the ideal range are not available.

MONITORING

Monitor respiratory and heart rate at home may be possible with many owners by teaching them to take the heart rate with a stethoscope. Also, monitoring of overall well-being (appetite etc) is important. The following details the specific monitoring for controlling heart rate using the ideal way, which is with 24-hour Holter monitoring.

1. Ideal monitoring for heart rate is 24-hour Holter monitoring repeated 7 to 10 days after beginning treatment and recheck parameters listed and assess for meeting target range
2. Adjust drug doses up or down to titrate the need to control fluid retention and heart rate
3. Recheck chemistry panel for renal function and electrolyte status 10 to 14 days after beginning medication
4. Check digoxin levels 8 to 12 hours after pilling 10 to 14 days after beginning medication. Repeat as needed.

5. Ideal to recheck thoracic radiographs and electrocardiogram at the time of the second Holter recording to assess heart rate response.
6. If the initial heart rate is more than 200 bpm, vigilant follow-up within one week is ideal with home monitoring on the days before this examination. Dogs with heart rates of greater than 200 bpm frequently require combination therapy.

CONTROVERSIAL POINTS

There are many controversial points with regards to the treatment of congestive heart failure and the specific drugs selected. The following are some controversial points.

1. Treatment with beta-adrenergic blockers is controversial at this stage of failure and may actually be contraindicated until failure is well controlled.
2. Treatment with pimobendan by initial studies shows promise for DCM, but the benefit for degenerative valve disease is unknown, although in the late stages of endocardiosis the disease is likely very similar.
3. The exact target heart rate for various breeds with different diseases and stages of failure is unknown. The recommendations here are only initial suggestions that need further evaluation and critical review.
4. Some people no longer like to use digoxin.

MANAGEMENT OF VENTRICULAR ARRHYTHMIAS

The treatment of ventricular arrhythmias (VA) has dramatically changed over the last 30 years in human medicine. Reading this literature and more critically evaluating our standard of care in dogs also has altered our approach to the management of VA. Decades ago recommendations for the treatment of VA revolved around the number of premature complexes identified by routine electrocardiography (ECG), but today treatment is reserved for VA that are judged to be truly 'dangerous.' Furthermore, the success or failure of long-term treatment is more critically studied by 24-hour ambulatory ECG monitoring (Holter monitoring). In this discussion the following will be addressed in practical terms discussing the medications that are available to most practitioners: (1) when should VA be treated (2) what are the most common diseases or circumstances that demand treatment, (3) what determines route of administration [intravenous (IV) versus oral (PO)] and what medications should be selected, and (4) how should the VA be monitored during therapy.

Ventricular arrhythmias should be treated when they result in clinical signs, tachycardiomyopathy or harbor the risk of death. Hemodynamic consequences of VA that cause clinical signs are related to hypotension. Sustained hypotension causes weakness, lethargy, exercise intolerance and, if severe and prolonged, syncope. The development of low systemic blood pressure that persists long enough to result in clinical signs is primarily related to ventricular tachycardia (VT) that is rapid and prolonged (sustained), and not to single or paired ventricular premature complexes. It is possible that the latter can lead to ventricular fibrillation (VF) when such beats fall within the vulnerable period of the T wave. This is known as R on T phenomenon. Although such timing of a premature complex can induce VF, how frequently this occurs in the dog has not been ascertained. Thus, the criterion to define the R on T interval that requires treatment in the dog is unknown. Polymorphic VA also have traditionally been viewed as more ominous than monomorphic VA; however, this is not necessarily true. Boxers with arrhythmogenic right ventricular cardiomyopathy (ARVC) 85% of the time have monomorphic VT and their risk of sudden death is high. Older dogs with mitral regurgitation can have single ventricular premature complexes that are polymorphic and for which the frequency of sudden death is low. In contrast, Doberman pinchers with dilated cardiomyopathy (DCM) do have polymorphic VT and a high incidence of sudden death. Therefore, the assessment of risk depends on the incorporation of multiple factors for each patient. It should be emphasized in this appraisal, underlying cardiac disease must be considered in addition to type of VA present. Animals can tolerate sustained and rapid VT for more prolonged periods if they have adequate myocardial function and are capable of compensating (eg, baroreceptor reflex) for the VT. Therefore, when there is underlying myocardial failure (eg, DCM, ARVC, substantial AV valve regurgitation) the need to suppress the VT is more important; however, because of additional physiologic issues like renal perfusion and concurrent drug medication, the treatment is more challenging. Importantly, when a tachyarrhythmia persists structural and electrical remodeling can develop that can be detrimental and actually induce myocardial failure. This has been proven experimentally in the dog and recognized clinically. That is, a dog that initially only has a tachyarrhythmia without myocardial failure will develop such if the rapid rate is not control. The myocardial failure can be permanent if the arrhythmia persists for a number of weeks or even days if the rate is very fast. Therefore, again, one of the major determinants of risk and need to treat rests in the rate of the arrhythmia. The faster and more sustained the arrhythmia, the more aggressive the treatment must be.

By examining the natural history of a diseases or the circumstances that are associated with VA, those that most often result in clinical signs or sudden death can be identified. Likely the two most common diseases that demand treatment for VT are ARVC in boxers and DCM in Doberman pinchers (and other afflicted breeds). Another breed with sudden death related to VT is the German shepherd. The most common circumstances that cause VT are traumatic myocarditis, myocarditis, and gastric torsion/volvulus.

The VT identified in boxers is most frequently rapid (rates exceed 250 bpm), monomorphic, and it is of a left bundle branch block pattern with an upright orientation in leads II, III, and aVF. Holter recordings have documented that often the VT that causes clinical signs occurs when the dogs are excited or exercising. The latter circumstances which are associated with increases in sympathetic tone are often the triggers for the VT. Importantly, controlling the triggers of arrhythmias can be as important in treatment as therapy to disrupt the substrate or mechanism of the arrhythmia. The mechanism of the VT in boxers is unknown. However, the origin of the VT, based on the morphology and the location of the pathology, is from the right ventricle. Recent studies raise the question of disruption of the intercalated disc proteins in affected boxers that could be an arrhythmogenic substrate. Boxers with polymorphic VA often have heart failure, while it is common to see rapid monomorphic VT in boxers with syncope alone. Also, Holter recordings of syncopal boxers has shown that in addition to the VT, some dogs have sinus pauses of greater than 8 seconds that are responsible for the clinical signs. Thus, treatment must be tailored to both arrhythmias. Studies do not exist to prove that treatment of the VT in boxers actually decreases the risk of death; although some work does support the use of certain drugs for the antiarrhythmic effect. Notably, just because a drug decreases the frequency of an arrhythmia, this does not insure that it will prevent sudden death.

Doberman pinchers with VA demanding treatment almost always have concurrent severe myocardial failure due to DCM. This is in contrast to the boxer. The polymorphic VT documented in Doberman pinchers may not be the cause of death as bradyarrhythmias have been documented as another fatal rhythm. Because these dogs are usually on numerous concurrent medications and their hemodynamic status is more fragile, the negative inotropic effect of the antiarrhythmic drug must be considered. Most ventricular arrhythmias are markedly affected by elevations in sympathetic tone and circulating catecholamines, and thus, often antiarrhythmics are either combined with beta-adrenergic blockers (mexiletine plus atenolol) or adrenergic blockade is a component of the specific drug (sotalol, amiodarone) used. In the Doberman pincher titrating the dosage of the drug to have an appropriate antiarrhythmics effect with the least negative inotropic consequence is difficult. In general the comments here apply to other breeds afflicted with DCM.

At first it may seem obvious how to determine whether IV medication is required; however, this is not always true and the wishes of the owner may not permit hospitalization. Dogs with VT and severe systemic hypotension that cause them to be moribund, weak, or repeatedly collapsing require IV treatment with the goal of conversion to sinus rhythm or slowing of the rate. Sometimes dogs in dire distress may be cardioverted if synchronization with the R wave is possible to avoid shocking on the T wave. Regardless of the type of VT, underlying disease or mechanism; lidocaine is the most common drug given IV for the treatment of VT in dogs today. The most common sequence of events is to administer one or several boluses of lidocaine at 1 to 2 mg/kg IV and follow this with a constant rate infusion (CRI) of lidocaine at 40 to 80 µg/kg/min. Most frequently CRI doses approximating 50 to 60 µg/kg/min are required to assure effectiveness. Caution should be used if the total bolus dosage approaches 6 mg/kg over a 15- to 30-minute period of time. Toxicity is recognized as twitching or seizures. Because the half-life of lidocaine is short the side effects dissipate rapidly, but IV diazepam might be required. The most common reason for lidocaine toxicity is miscalculation of the dose in terms of decimal point location. Consequently, clear written instructions with sample doses for the size of the animal are ideal for checking calculations in the emergency situation. Although lidocaine is the most commonly used drug, some prefer to use procainamide IV as a bolus (10 to 15 mg/kg slowly) followed by a CRI (25–50 µg/kg/min). This drug is uncommonly used PO, but still remains as a possible drug for critical VT. Bolus treatment must be delivered with a slower push than lidocaine because more problems can develop with systemic hypotension, although lidocaine doses produce a momentary drop in systemic blood pressure even in dogs with normal myocardial function.

Because lidocaine has multiple antiarrhythmic mechanisms it can be effective regardless of disease or circumstance. However, when lidocaine is ineffective, understanding the reasons for failure is important and alternate medications are needed. Sometimes the reason for a lack of response is that the dose used is too low; thus, up-titration is important to eliminate this as an explanation for failure. The antiarrhythmic effects of lidocaine are hindered in the presence of hypokalemia or acid-base imbalance. After these examinations, a trial with procainamide is logical. Other drugs can be tried as well, but availability is a major concern. When a drug is selected to treat VT, whether IV or PO and the arrhythmia persists the diagnosis of the rhythm may be incorrect. Although less frequent, wide QRS supraventricular tachycardias should be considered. If additional antiarrhythmic drugs are not available for IV trial, then PO medication and hemodynamic support can be given. Sotalol given PO in such situations has converted dangerous VT in several hours when usual IV medications failed. Finally, some VT rhythms are 'malignant' and will not terminate or slow. This happens with severe myocarditis, myocardial infarction or myocardial neoplasia.

Oral medication is used when the VT is not immediately life-threatening. The definition of life-threatening is determined by both the type of VT and the hemodynamic response of the dog. Some dogs will appear undisturbed by a rapid VT particularly if they have preserved myocardial function and the VT is intermittent. To treat with oral medication will usually suffice; however, there are management issues that are critical to knowing the effectiveness of the drug and the dosage selected (see below). Other dogs may be presented with a history of syncope and the cause is suspected to be intermittent VT based on ECG monitoring and Holter monitoring. The most commonly used drugs given PO today for the treatment of VA are sotalol (2.0 to 2.5 mg/kg BID), mexiletine (4 to 8 mg/kg TID) combined with atenolol (0.5 to 1.0 mg/kg BID), or amiodarone. Amiodarone is commonly used in human medicine; however, thus far in the treatment of dogs with VT the published data has emphasized the problems, with little evidence of effectiveness against the VT. It is vital to comment on the doses given. These are regarded as 'usual' and not exact for a particular patient. Antiarrhythmic drugs and adrenergic blockers must be titrated to effect and with the intent to avoid side effects.

When VT is being treated in the intensive care situation with constant ECG monitoring during IV treatment, effective treatment is ideally identified by conversion to a sinus rhythm. Still, critical evaluation is required if the VT occurs in intermittent runs to be convinced that the drug actually caused the conversion and it was not just by chance. With the advent of greater digital storage capacity on computers, electronic ECGs that continuous record the ECG of a critical patient can be effectively evaluated instead of the 'by chance' paper recording. Selected electronic ECG systems currently available can store one hour of data at a time and then be reset. Likely such system will only improve. When dogs are treated by the IV route a positive response should be seen within minutes to bolus therapy and maintained with CRI. If such treatment is given, and no effect is documented in such a time frame, the medication plan should be reconsidered. After stabilization of the dog with IV treatment, transition to oral medication is required if deemed necessary. For this transition, usually beginning the oral medication approximately 1 to 3 doses before stopping the CRI is effective. There is a cross over time when either excessive medication may cause side effects or too little permits the arrhythmia to return. Importantly, just because a drug is effective IV, does not mean that it will be effective given orally, nor that a drug with similar action will be effective. It is not uncommon to have a dog treated with lidocaine in ICU and then switched to sotalol PO.

To know if a drug is having (1) no effect, or (2) an antiarrhythmic or (3) a proarrhythmic effect, Holter monitoring is required. In order to make this judgment a baseline recording is required. Most often such a recording can be made for 24 hours and treatment started immediately after removing the monitor. However, in some dogs the VT may be too dangerous to permit a full 24-hour recording, although the condition of the dog is not so severe that admission to intensive care for IV treatment is required. For these dogs, the longest baseline recording that is felt to be safe is performed and the animal started on medication after this time. Because it is not known that medication will indeed improve the VT, it can be argued that the baseline is as important as the treatment. The latter is true because some dogs do experience proarrhythmic effects from drugs used as antiarrhythmic medication. Therefore, the standard of care for the treatment of VA is as follows: (1) obtain baseline 24-hour Holter monitor recording in the environment where the medication will be administer (home), (2) treat with the selected medication and dosage, (3) recheck 24-hour Holter recording in 7 to 10 days after questioning to insure compliance, (4) evaluate for change in frequency or severity of the VA and determine if treatment is successful or not. If the VA counts and severity are not altered the dosage of medication is usually increased and then the Holter recording repeated 7 to 10 days later. If the VA are not suppressed then an alternative or additional medication can be given. When combinations of antiarrhythmic drugs are used (eg, sotalol plus mexiletine) caution and close monitoring are absolutely needed to avoid side effects.

Because most dogs undergoing treatment for VT have underlying structural or functional disease monitoring requires attention to these aspects of cardiac function. Thus, additional monitoring with thoracic radiography and echocardiography are common. Moreover, examination of blood chemistry profiles in such cases is warranted. It should be stressed that if an owner reports any problems that are new after a medication has been started, it is wisest to blame the drug first. Assessment of side effects is important and only if a critical approach is taken can serious problems be avoided. The most common problems reported are vague and relate to overall well-being in addition to complaints of anorexia. Other complaints reported include twitching and change in behavior.

HEART FAILURE MANAGEMENT

N. Sydney Moïse, DVM, Diplomate ACVIM
College of Veterinary Medicine
Cornell University, Ithaca, NY

The treatment of heart disease in dogs is very controversial. Which drugs to use and when to institute treatment occupy many discussions among veterinary cardiologists. The pros and cons of treatment are supported by some clinical trials and many opinions. Likely there is some truth to most of the views and it is the perspective of the type of patient (type and stage of disease) that is different. Moreover, treatment must be individualized. During this session some of the aspects of cardiac drugs that are not as commonly discussed will be presented as they pertain to treatment. The use of these drugs will be placed into the context of clinical case examples. The most common diseases that are considered in dogs are degenerative valve disease and myocardial failure associated with dilated cardiomyopathy.

Heart failure must be staged in order to adjust treatment. To accurately know the stage or severity of disease is difficult because (1) symptoms are unknown. Only clinical signs can be assessed in animals. Therefore, earlier signs of disease are missed. (2) Variation in tolerance to heart failure or recognition of clinical signs can place an animal in the wrong stage, (3) Diagnostic tests for earlier stages of disease are insensitive to the presence of disease, and (4) no clinical trials to really assess the definitions of staging heart failure exists (repeatability of staging heart failure by trained observers). Therefore, in veterinary cardiology we have adopted in part the staging methods from human medicine and these are not optimal. When the various clinical trials in veterinary medicine are compared, the validity may not be sound for such comparisons because different methods of staging the disease progression were used. The New York Heart Association Classification of Heart Failure is summarized as:

1. Class 1 Heart disease - no symptoms
2. Class 2 Heart disease - symptoms only with vigorous exercise
3. Class 3 Heart disease - symptoms with routine daily activity
4. Class 4 Heart disease - symptoms at rest

Also, an additional classification considered in human medicine was recently developed to complement the NYHA scheme and is summarized as:

1. High risk for heart failure but no apparent structural abnormality of the heart disease
2. Structural abnormality present but no symptoms of heart failure
3. Structural abnormality and current or previous symptoms of heart failure
4. End-stage symptoms and refractory to treatment

An attempt was made to improve the system in canine patients with the International Small Animal Cardiac Health Council Classification of Heart Failure and it is summarized as:

1. Class I – Heart disease is present, but no clinical signs. Abnormalities may be seen by the ECG, radiograph, or echocardiogram.
2. Class II – Some clinical signs are present at rest or with mild exercise.
3. Class III – Clinical signs critical with dyspnea, ascites, and marked exercise intolerance.

In the clinical trials in veterinary medicine there has been a collapsing of the staging and a simplification such that general conclusions may not apply to subgroups and individuals. Often the NYHA classification collapses into two groups of (1) clinical signs or (2) no clinical signs. In some studies the pivotal classification is by thoracic radiographs where by the dog is categorized into 'failure' completely on the basis of the radiographic appearance of pulmonary edema or not. Consequently, this will be an evaluation of severe cardiac decompensation.

The following are drugs that are used in the treatment of heart failure. Following each drug the controversial points are stated.

- **Furosemide.** What dose should be used? Standard recommendations have been made but some advocate much higher doses. Should it only be used with overt edema? Does diuretic resistance exist in the dog? In severely decompensated cases is a constant rate infusion better than boluses?
- **Spironolactone.** Will this old drug help dogs? This is an aldosterone-receptor blocker that is known as a potassium-sparing diuretic. However, it is not for its diuretic effect that spironolactone has gained attention lately, instead it is because of the antifibrotic effect and prolongation of life that has been documented in humans. Some preliminary studies in dogs seem promising. If the use of spironolactone is for its antifibrotic effect, then the diseases that we treat should have fibrosis as a part of the pathology. Further study is needed to know if positive benefits really exist.
- **Inodilators.** The most common drug in this category used to date in veterinary medicine is pimobendan. Another drug in this category is levosimendan. These drugs have two effects: increased calcium sensitivity and increased cAMP activity. The amount of each varies with the specific drug and the dose. A great deal of attention has been given to this class of drugs in recent years. Many persons give positive testimonials to the effectiveness in dogs with systolic dysfunction, yet others warn of its dangers. Studies have indicated that pimobendan has a beneficial effect particularly in dogs with systolic dysfunction. Some dogs with systolic dysfunction can have marked improvement when treated with pimobendan. There is some concern and

controversy about using pimobendan in dogs early in disease when systolic function is not depressed. A recent clinical trial was conducted in Europe to assess the use of pimobendan in dogs with mitral regurgitation. The results of the trial are pending. Other clinical trials evaluating the use of levosimendan are also underway. These drugs are similar, but they do have important differences that may have clinical relevance.

- **Angiotensin enzyme-converting inhibitors (ACEI).** Strong opinions have been voiced concerning the use of ACEI without pulmonary edema. When should this group of drugs be used? Is there any difference between the various types of ACEI? Is there a way that all the clinical trial is actually compatible? ACEI drugs decrease serum ACE activity and aldosterone levels, but increase plasma renin activity. Some of the –pril drugs may have more effect on the local ACE system than the systemic. Some are prodrugs demanding conversion by the liver to the active form and some are secreted more by the kidneys than metabolized by the liver. These drugs do have different durations of action and so this is an important point in medicating the patient as to the interval of dosing.

    - Enalapril (Vasotec)
    - Lisinopril (Zestril, Prinivil)
    - Benazepril (Lotensin)
    - Quinapril (Accupril)
    - Ramipril (Altace)
    - Fosinopril (Monopril)

ACEI drugs are given to decrease the RAAS system. This will decrease aldosterone which then decreases sodium retention and consequently water retention. Also high aldosterone levels cause excretion of potassium and can mediate with angiotensin II inflammation and fibrosis along with causing a loss of baroreceptor response. But there are other means by which aldosterone is elevated that 'fight' this counter action of the ACEI drugs. These include catecholamines, endothelin I, and arginine vasopressin (ADH). Do clinical trials support the use of ACEI in heart failure? Most trials support the use of ACEI in dogs, particularly when heart failure is present and most likely when there is evidence of cardiomegaly. Some breeds may have different responses to ACEI. Moreover, ACEI are not started in dogs that have minimal disease and no cardiomegaly.

- Positive inotropes (eg, digoxin). Some cardiologists do not believe in digoxin. Others do believe that it can help patients. The differences of opinions mean that there are likely more than one way to treat heart failure and one path of therapy includes digoxin, while another path does not. There are some positive actions of digoxin that support its use. These include restoring restores autonomic balance, mild positive inotrope, inhibition of rennin, and decreasing sinus heart rate and ventricular response in atrial fibrillation (AF) which is common in heart failure. To effectively control heart rate in AF it is often necessary to use drugs such as long-acting diltiazem in conjunction with digoxin. Digoxin is used orally and not intravenously today. The dose is lower than what has been used in the past. Currently, we are using 0.003 mg/kg twice daily based on LEAN BODY WEIGHT. Also, our serum level that we strive for to say that the animal is titrated to the dosage that we desire is lower than what it has been in the past. We use approximately 0.7 to 1.0 ng/dL as our target range. The older range was 1 to 2 ng/dL, but this caused more adverse clinical signs.
- **Antiarrhythmics for common arrhythmias seen in heart failure.** The most common arrhythmia treated is atrial fibrillation. A point that needs to be emphasized is the use of 24-hour ECG (Holter) monitoring for the assessment of the heart rate and rhythm in atrial fibrillation.
- **Beta-adrenergic blockade.** The use of this category of drugs is the one that has the least clinical experience despite the theoretical reasons that we should use beta-blockers early in disease. The three most common are carvedilol, bisoprolol, and metoprolol.

When treating animals with heart failure we usually do not use a single drug. Heart failure must be attacked from different angles given the complexity. There are different ways to 'attack' and this is likely why different combinations of drugs can work. Some of the most common combinations include the following. Be aware that the way that we treat heart failure is evolving and changing. This is because we do not have a perfect method to solve the many problems.

FAINTING: BAD HEART OR BAD BRAIN?

Rebecca L. Stepien, DVM, MS, Dipl ACVIM (Cardiology)
School of Veterinary Medicine
University of Wisconsin, Madison, WI

Sudden episodic collapse may be associated with many disease conditions, but cardiovascular or neurologic diseases are the most common etiologies. Most often, the patient is fully recovered at the time of examination and may never manifest the collapsing behaviors in the presence of the clinician. Despite the episodes typically causing great consternation in the clients observing them, the clients are often unable to accurately describe the incident, are at a loss for critical details and may offer information that tends to cloud the picture rather than illuminate it. In these situations, prioritization of differential diagnoses and development of a diagnostic plan may be difficult.

The most important parts of the investigation occur before any diagnostic tests are performed. Because the patient frequently will not demonstrate the behavior in front of the clinician, the pertinent information must come from the owner of the pet (through the history) and from the pet itself (through observation and physical examination). Analysis of the signalment, history and physical examination (PE) findings will determine what type of further testing is required and the logical order of the tests.

DIFFERENTIATION OF SYNCOPE AND SEIZURE

Syncope is often defined as transient loss of consciousness accompanied by loss of postural tone and associated with a spontaneous recovery. Typically, there is little warning other than a brief moment of dizziness or nausea, the episode usually lasts < 1 minute and recovery to normality or near-normality occurs within minutes. During the event, the observer may describe their pet as limp or stiff ("all stretched out"), but there is no repetitive motion reported in most cases. In contrast, a seizuring animal typically exhibits motor activity during the event (i.e. paddling, scrabbling motions, chomping, drooling). Prodromal events associated with seizures may precede the event by minutes to days, and often include behavioral changes, which may be predictable enough to "warn" observant owners that an event is coming. After the seizure event (which may have required medical therapy to terminate), recovery may be prolonged, with animals showing behavior changes or disorientation for minutes to hours. Event duration of more than 3 minutes is more consistent with seizure than syncope.

History: What Can The Event Observer Tell Us?

Before a specific history regarding the event is taken, it is helpful to quickly review the patient's general health with the owner, with particular and meticulous attention to concurrent diseases and therapies for those diseases. In elderly patients on multiple medications, especially cardiovascular medications, drug-related orthostatic hypotension is a common cause of episodic weakness or syncope. The risk of hypotension in patients receiving diuretics and vasodilators is exponentially increased if the patient is not eating well or is anorexic.

The core of event investigation is the description of the event. The best information regarding the circumstances and substance of the event comes from a direct observer. If the observer is not present at the consultation, a phone call to the observer during or after the examination is needed. After recording a full spontaneous description of what the observer saw during the event, the clinician can elicit further details with a few focused, precise questions. These questions should be asked regardless of whether the initial description appeared to "cover" the information. Questions of limited scope that direct attention to one particular aspect of the event frequently allows the observer to recall details lost in the excitement of the overall event. In addition, the observer may not be aware that certain details are important until asked. Examples of focused questions that may be helpful are presented in Table 1.

Physical Examination: What Can The Patient Tell Us?

The signalment of the patient, particularly the breed (primarily dogs) and age (dogs and cats) can be very helpful in directing the subsequent investigation. Idiopathic epilepsy or congenital heart diseases like pulmonic stenosis are most commonly diagnosed in young animals, and certain breeds may be more likely to be affected with certain anomalies. In cases of syncope, some breeds of dogs (Doberman pinschers, Boxers, Schnauzers) have an increased incidence of cardiac diseases commonly associated with syncope-inducing arrhythmias.

Beyond observations of signalment, a thorough physical examination (PE), including retinal examination, is mandatory. Once a general PE is complete, a second, more specific examinations focusing on the cardiovascular and central nervous systems are performed. Any evidence of cardiovascular abnormality, including abnormal heart rate or heart rhythm, detection of extra heart sounds or murmurs, or detection of poor perfusion via palpation of weak peripheral pulses or observation of abnormal capillary refill time is an indication for further investigation of the cardiovascular system. Findings that focus attention on the central nervous system as the cause of the event in question include findings of intracranial lesions (focal cranial nerve deficits, mentation changes) or evidence of hypertension (retinal vascular congestion, retinal hemorrhage or detachment).

APPROACH TO THE PATIENT WITH SYNCOPE OR SEIZURE

A thorough history and PE should be completed on *every* patient presented for evaluation of a sudden collapse event. Although findings of these two important examinations usually categorize events as syncope or seizure and guide further testing in most cases, there are few important exceptions. Right to left cardiac shunts

Table 1. Focused Questions for Observers of Sudden Collapse Events

Question	Syncope	Seizure
What was the pet doing when the event occurred?	• Activities involving exertion, straining (urination, defecation, cough), stress or sudden pain was involved, syncope is more likely. • Not associated with rest or sleep.	• Any activity or none (rest/sleep)
What was the posture/degree and type of motion of the pet during the event?	• Limp/motionless • Stiff/motionless	• May show "classic" paddling/chomping behavior, head bobbing, drooling • Movements may be misconstrued as "trying to get up"
Did the pet look at you when you called his/her name?	• During syncopal event, no recognition, sudden return to responsiveness. • Presence of recognition may indicate weakness rather than syncope.	• During event, no evidence of recognition • Return to full responsiveness may be slow
How long did the event last?	• 1-2 minutes	• Any length, but event length > 3 minutes is likely seizure rather than syncope

leading to polcythemia may cause either seizures (if PCV > 75%) or exertional syncope (when right-to-left shunting is exacerbated by decreased peripheral resistance during exercise). Occasionally, prolonged hypoxia during syncope may result in seizure activity ("convulsive syncope") and some partial seizures appear as syncope ("temporal lobe syncope"). The latter two exceptions appear to be rarely noted in veterinary patients.

General Approach to Suspected Seizure

Patients with evidence of intracranial disease on PE can be investigated further with imaging (eg, MRI) or evaluation of cerebrospinal fluid. Seizuring patients should also be investigated for metabolic causes of seizures, including biochemical disturbances and polycythemia. If metabolic derangements leading to seizures are discovered, a thorough investigation of the underlying cause is indicated. Lastly, patients with a history of seizures should have their systemic blood pressure (BP) evaluated for evidence of systemic hypertension. The most common overt clinical sign of severe systemic hypertension is intraocular or retinal hemorrhage or retinal detachment, but systemic hypertension may also be associated with intracranial hemorrhage or edema that may lead to seizures. Since this evaluation is aimed at identifying hypertension as the underlying cause of seizures, BP measurement should be performed when the animal is clinically normal (ie, not immediately following the event).

General Approach to Suspected Syncope

Examination of patients suspected of syncopal events begins with the careful history and PE detailed above. In addition, ALL patients with syncope should have a resting electrocardiogram (ECG) recorded, regardless of auscultation findings. In some cases, abnormal rhythms responsible for syncope may have a normal heart rate by auscultation. In addition, ECG recordings may reveal evidence of cardiac disease (eg, conduction disturbances) even if overt arrhythmias are not detected. Evaluation of BP in patients with collapse events, especially those receiving cardiovascular medications, is also routinely recommended. A complete cardiac assessment is indicated when any of the above findings are abnormal (auscultation, ECG, BP) or reveal concurrent disease or medications likely to affect blood pressure. Common cardiovascular causes of syncope are outline in Table 2.

RATIONAL DIAGNOSTIC TESTING FOR PATIENTS WITH SUSPECTED CARDIOVASCULAR SYNCOPE

Once the initial cardiovascular PE, ECG, and BP evaluation are completed, thoracic radiographs and an echocardiogram are recommended to diagnose or exclude cardiac disease from the list of possible etiologies. If a significant cardiac abnormality/disease is identified, that abnormality should be addressed first and thoroughly, and any pre-existing medications should be reviewed and their possible contribution to the problems evaluated.

Ambulatory Electrocardiography

The possible contribution of arrhythmias to the genesis of syncopal events can be further investigated through the use of ambulatory electrocardiography:

- **Telemetry observation:** Hospitalized patients may be monitored with telemetric electrocardiography

Table 2. Common Cardiovascular Causes of Syncope

Cause	Comment
1. Sudden decrease or loss of cardiac output	
• Arrhythmia	
• Bradyarrhythmias	Sinus arrest, 2nd /3rd degree heart block
• Tachyarrhythmias	• Supraventricular or ventricular tachycardia
• Obstruction to outflow	
• Pulmonic stenosis	• Most common with severe pulmonic stenosis
• Pulmonary hypertensio	• Syncope may be the only presenting clinical sign
• Aortic stenosis	• Most common with severe stenosis. • Syncope may also be due to ventricular arrhythmias
• Pulmonary thromboembolism	• Typically accompanied by dramatic dyspnea
• Inadequate preload (ventricular filling pressure)	
• Cardiac tamponade	• In the presence of severe pericardial effusion or moderate pericardial effusion if abnormal pericardial sac or concurrent dehydration
• Mitral or tricuspid stenosis	
• Extreme dehydration	• May be secondary to overuse of diuretics • May be complicated by electrolyte abnormalities
• More complicated and rare congenital malformations	• E.g. cor triatriatum dexter or sinister
2. Situational hypoxia	
• Pulmonary edema (congestive heart failure)	Usually responsive to resolution of pulmonary edema
• Pulmonary thromboembolism	• Typically accompanied by dramatic dyspnea
3. Inadequate BP with normal cardiac output	
• Drug-related hypotension	• More of a problem in elderly patients
• Neurally-mediated syncope	• Diagnosis of exclusion
• Autonomic abnormalities associated with severe systemic diseases	• E.g. sepsis, neoplasia

during the hospitalization; the ongoing tracings are monitored for suggestive or diagnostic abnormalities

- **Holter recorders:** Portable monitors worn by the patient in a harness or bandage; most monitors record approximately 24 to 48 hours of electrographic information. Most helpful in patients in whom events are frequent or information regarding the total number of arrhythmias in 24 hours is needed.
- **Event monitors:** portable monitors that are worn for an extended period of time and are activated by the owner when an event is observed. Helpful for infrequent events and to exclude arrhythmia as a cause of events.
- **Implantable recorders (eg, Reveal™):** Digital ECG recorders that are implanted subcutaneously over the heart. These recorders are well tolerated and may be left in place indefinitely (or until the end of battery life). Sample ECGs are recorded automatically when an abnormal rhythm is sensed, or the recorded may be activated by the owner during an event. The data is downloaded with an external "wand" sensor held just above the skin over the monitor. Availability of these monitors for veterinary use is limited at present.

Table 3. Recommendations for Further Testing in Syncopal Patients

Results of Cardiovascular Testing	Recommendations
• Results of basic testing reveals clear rhythm abnormality	• Treat underlying arrhythmia
• Results of basic testing reveals structural heart disease with or without heart failure	• Rule out complicating arrhythmias, treat as needed • Optimal therapy of heart disease/failure
• No abnormalities on auscultation, resting ECG or BP assessment • Canine patient is not an "at-risk" breed*	• If first time event and patient is clinically normal, consider monitoring over time with client counseling regarding "what to watch for" • If events are recurrent, consider event monitor
• Canine patient is "at risk" breed* • No abnormalities on auscultation, resting ECG or BP assessment	• Ambulatory ECG monitoring strongly recommended
• Cardiovascular disease is present • Hypotension is present • Cardiovascular medications are in use	• Assess and address hydration and electrolyte abnormalities • Address cause(s) of anorexia, if present • Temporarily discontinue or alter doses of medications as needed

A PRACTICAL APPROACH TO ACID–BASE ABNORMALITIES

Matthew W. Beal, DVM, Diplomate ACVECC
College of Veterinary Medicine
Michigan State University, East Lansing, MI

Acid–base disorders are COMMON in critical illness. Arterial and venous blood gas analysis provides the veterinary health care team with rapid access to valuable diagnostic information about their patients. Coupled with a complete medical history, full physical examination, electrolyte profile, packed cell volume (PCV), total solids (TS), glucose, and blood urea nitrogen (BUN), determination of the acid–base abnormalities present in an individual can rapidly narrow the list of differential diagnoses for the underlying medical problem(s) facilitating a rapid movement towards focused diagnostic testing and therapeutic intervention.

Recent technological advances have brought affordable blood gas, electrolyte, lactate, blood glucose, ACT, and creatinine analysis to veterinarians in a point-of-care setting.[a,b] This article provides the reader with an introduction to blood gas analysis for determining the acid–base status of the patient presented with critical illness.

SAMPLING

Arterial blood gas samples are required for determining all aspects of the patient's acid–base and respiratory status. Venous blood gas specimens will provide information surrounding the metabolic side of the patient's acid–base status, but cannot be used as a substitute for arterial blood gas analysis (described below), nor can it be used for calculation of pulmonary function parameters such as the alveolar–arterial oxygen tension gradient. This being said, the author frequently acquires venous blood gas data coupled to electrolyte, and other chemical analysis (BUN/lactate) in many patients presenting with critical illness not affecting the respiratory system. When coupled with a PCV/TS/blood glucose, venous blood gas/electrolyte analysis/ biochemical analysis provides the attending clinician with an excellent database that will enable him or her to immediately narrow the list of differential diagnoses and make appropriate therapy decisions while directing additional diagnostic testing.

Specimens collected for arterial or venous blood gas analysis must be kept anaerobic. This is accomplished by removing all air from the sampling syringe and then using a stopper or provided cap to seal the tip of the needle or syringe, respectively.

Samples for venous blood gas analysis may be taken from any vein. The most commonly utilized sites are the jugular, cephalic, and saphenous veins. Sampling of blood from the arterial system is an acquired skill that requires practice to perfect. The most commonly sampled sites are the dorsal pedal (metatarsal) and femoral arteries. Caution should be exercised and samples should not be taken from the femoral artery or the jugular vein in patients with moderate to severe hemostatic abnormalities or evidence of spontaneous hemorrhage.

A strong knowledge of regional anatomy is the key to sampling from the dorsal pedal artery. The dorsal pedal artery crosses from lateral to medial (very superficially) just below the tarsus where it then travels between metatarsals II and III (Figure 1). The most distal site at which the artery can be palpated is optimal for sampling. This location is usually where the artery dives between metatarsals II and III (see circle in Figure I). Equipment necessary for sampling from the dorsal pedal artery is an arterial blood gas syringe[c] or a preplaced arterial catheter. Arterial blood gas syringes are vented, making it unnecessary for the clinician to aspirate the plunger while sampling. Sampling can be performed with a heparinized syringe (aspirate heparin into syringe and evacuate as much as possible), but the procedure is much more challenging because the syringe must be aspirated. The procedure for sampling from the dorsal pedal artery is as follows:

1. Position the animal in lateral recumbency with the limb to be sampled down.
2. Clip the hair from the area and apply a full surgical scrub.
3. Have an assistant place a few fingers behind the hock to help immobilize it. Pressure should NOT be applied around the circumference of the hock.
4. Wear gloves and palpate the dorsal pedal artery along its entire course.
5. Insert needle (25- to 22-gauge) through skin just distal to the site at which the artery can be palpated at the angles indicated in Figure I. Keep in mind that the artery is very superficial.
6. Advance the needle firmly in 1mm increments until blood is noted in the needle hub.
7. Once blood is seen in the hub, immobilize the syringe.
8. The syringe should fill in 5 to 10 seconds (depending on the size of the patient and the size of the sample acquired).
9. Withdraw the needle and apply a compressive dressing for 10 to 15 minutes.
10. Handle sample anaerobically and analyze sample immediately.

BLOOD GAS ANALYSIS; ANSWER THE QUESTIONS!

When beginning to work through an acid-base problem, it is first important to recognize that there are three main chemical "players" that largely determine the pH of the blood. These include hydrogen ion ([H+]), the partial pressure of CO_2 dissolved in the arterial blood ($PaCO_2$), and bicarbonate (HCO_3). Hydrogen ion should be considered a fixed acid and will thus promote acidemia, $PaCO_2$ should be considered a volatile acid and will also promote acidemia, while bicarbonate should be considered a base and will promote alkalemia. [H+] and bicarbonate concentration are largely regulated

Figure I. Dorsal pedal arterial anatomy (left hind limb)

by the kidneys while $PaCO_2$ is regulated by the respiratory system through ventilation. When evaluating an arterial blood gas, the bicarbonate concentration will tell us about the metabolic side of our acid–base problem while the $PaCO_2$ will tell us about the respiratory side of our acid–base problem.

Normal biologic processes function best around a neutral pH (7.35–7.45). As a result, the pH of the blood is tightly regulated around a pH of 7.4. When the pH deviates due to a pathologic process, compensatory mechanisms come into play to minimize the change and to compensate for it. The respiratory system can rapidly compensate for metabolic abnormalities and the renal system is able to compensate over time for respiratory acid-base abnormalities.

Despite the normal pH ranging from 7.35–7.45, for the purposes of acid–base analysis, normal pH will be considered 7.40. Patients with a pH less than 7.4 are acidemic and those with a pH greater than 7.4 are alkalemic. Normal bicarbonate concentration will be considered to be 22mEq/L and normal $PaCO_2$ will be considered 35 mmHg.

The acid–base disturbances and the compensatory change that occurs are shown in Table 1. Table 2 demonstrates appropriate compensation for a given acid–base disturbance.

Answering the following three questions will facilitate the diagnosis of the underlying acid–base problem from which a list of differential diagnoses can be formulated such that additional diagnostic testing can be directed to make a definitive diagnosis.

Table 1. Acid–Base Disturbances and the Compensatory Change that Occurs

Disturbance	**pH**	**Mechanism**	**Compensatory Response**
Metabolic Acidosis	↓	↓ HCO_3 / ↑ [H+]	↓$PaCO_2$ (Hyperventilation)
Respiratory Acidosis	↓	↑$PaCO_2$ (Hypoventilation)	↑HCO_3
Metabolic Alkalosis	↑	↑HCO_3 / ↓[H+]	↑$PaCO_2$ (Hypoventilation)
Respiratory Alkalosis	↑	↓$PaCO_2$ (Hyperventilation)	↓ HCO_3
Mixed Disturbance	↑ or ↓	Variable	Variable

Table 2. Appropriate Compensation for a Given Acid-Base Disturbance

Disturbance	**Expected Compensatory Response**
Metabolic acidosis	Exp. P_aCO2 = 35 – [(22 – HCO_3) X 0.7]+/-3 mmHg
Metabolic alkalosis	Exp. $PaCO2$ = 35 + [(HCO_3 – 22) X 0.7]+/-3 mmHg
Respiratory acidosis (acute <24 hr)	Exp. HCO_3 = 22 + [(P_aCO_2 – 35)X0.15]+/-2 mEq/L
Respiratory acidosis (chronic >24 hr)	Exp. HCO_3 = 22 + [(P_aCO_2 – 35)X0.35]+/-2 mEq/L
Respiratory alkalosis (acute <24 hr)	Exp. HCO_3 = 22 – [(35 – P_aCO_2) x 0.25]+/-2 mEq/L
Respiratory alkalosis (chronic >24 hr)	Exp. HCO_3 = 22 – [(35 – P_aCO_2) x 0.55]+/-2 mEq/L

Question 1: What is the pH?

There are five possible acid–base abnormalities (metabolic acidosis, metabolic alkalosis, respiratory acidosis, respiratory alkalosis, mixed disturbance). Determination of the pH will narrow the possibilities to three. The primary acid–base disturbance has to be one that causes the pH to move in the given direction. For example, if the pH is 7.25, then the primary acid–base disturbance has to be one that causes acidemia. These include metabolic acidosis, respiratory acidosis, and a mixed disturbance. Conversely, if the pH is >7.40, then the primary acid–base disturbance must be metabolic alkalosis, respiratory alkalosis, or a mixed disturbance.

Question 2: Which direction have the bicarbonate and the $PaCO_2$ moved?

Remember that normal bicarbonate concentration is considered 22mEq/L and normal $PaCO_2$ = 35 mmHg. Remember that bicarbonate tells us about the metabolic side of our acid–base equation and behaves like a base and that $PaCO_2$ tells us about the respiratory side of our acid-base equation and behaves as a volatile acid. Table 3 describes how changes in $PaCO_2$ and bicarbonate tend toward specific acid–base disturbances.

If, for example, the patient's pH is 7.25, he is acidemic. If the bicarbonate is low, this would imply that part of his acid–base problem is metabolic acidosis. If the $PaCO_2$ is also low, this would imply that he also has respiratory alkalosis. Because the pH is low, the PRIMARY acid–base disturbance must by metabolic acidosis (or mixed). Question number 2 will effectively narrow the list of possible acid-base disturbances to two (from an original of five possibilities).

Question 3: Is appropriate compensation occurring?

As mentioned previously, deviation of the pH from normal is minimized through compensatory responses. Equations (see above) have been developed that describe appropriate levels of compensation for given acid–base disturbances. If the compensatory change is in excess of or smaller than the expected change (or in the opposite direction of the expected change), a mixed disturbance is present. With completion of question 3, the acid–base problem is solved.

EXAMPLE

There is no better strategy for perfection of acid-base problem solving than to practice. The following example illustrates solving of a common clinically encountered acid-base problem. This arterial blood gas sample is collected from a 9-year-old female spayed mixed breed dog that presents with the complaint of acute collapse.

pH: 7.27
$PaCO_2$: 27 mmHg
HCO_3: 12 mEq/L

Question 1: What is the pH?

The patient is acidemic. Thus, the primary acid–base disturbance must be metabolic acidosis, respiratory acidosis, or a mixed disturbance.

Question 2: Which direction have the bicarbonate and the $PaCO_2$ moved?

The bicarbonate is low (a deficit of base). Bicarbonate tells us about the metabolic side of our acid–base problem. The low bicarbonate suggests that a component of our acid–base disturbance is metabolic acidosis.

The $PaCO_2$ is also low. $PaCO_2$ tells us about the respiratory side of our acid–base problem and because $PaCO_2$ behaves as a volatile acid, a low $PaCO_2$ suggests that a component of our acid-base problem is respiratory alkalosis.

Because the pH is low, metabolic acidosis must be the primary acid–base disturbance. However, a mixed disturbance is also possible.

Question 3: Is appropriate compensation occurring?

The compensatory response for metabolic acidosis is hyperventilation (respiratory alkalosis). Our patient appears to be hyperventilating (as expected). Choosing the equation

$$(\text{Exp. } P_aCO_2 = 35 - [(22\text{-}HCO_3) \times 0.7] \pm 3 \text{ mmHg})$$

that describes the expected change in $PaCO_2$ for the decrease in bicarbonate seen in a metabolic acidosis reveals that the expected range of $PaCO_2$ in this patient is 25 to 31 mmHg. Our patient's $PaCO_2$ is within the expected range. Thus, the diagnosis for this acid–base problem is metabolic acidosis. Had the $PaCO_2$ been <25 mmHg or >31 mmHg, a diagnosis of a mixed disturbance would have been made. A list of possible differential diagnoses for a dog that presents with metabolic acidosis is shown in Table 4.

A complete medical history and full physical examination coupled with basic ancillary diagnostic tests often reveal the specific etiology for a given acid–base disturbance.

Table 3. Changes in $PaCO_2$ and Bicarbonate and Specific Acid–Base Disturbances

Change	Acid-Base Abnormality	Why?
$PaCO_2$ > 35mmHg	Respiratory acidosis.	Retention of volatile acid.
$PaCO_2$ < 35mmHg	Respiratory alkalosis.	Blowing off volatile acid.
HCO_3 > 22mEq/L	Metabolic alkalosis	Retention of base.
HCO_3 < 22mEq/L	Metabolic acidosis	Use (buffering) / loss of base.

Table 4. Differential Diagnoses for Specific Acid–Base Disturbances

Acid–Base Disturbance	Etiology / Differential Diagnoses
Metabolic acidosis	▪ Lactic acidosis ▪ Diabetic ketoacidosis ▪ Failure to excrete [H+] as is seen in renal failure and hypoadrenocorticism ▪ Ethylene glycol metabolites and aspirin toxicity
Metabolic alkalosis	▪ GI obstruction oral to the major duodenal papilla ▪ Vomiting ▪ Gastric suctioning ▪ Furosemide therapy
Respiratory acidosis	▪ Hypoventilation (various causes)
Respiratory alkalosis	▪ Hyperventilation (various causes)

APPROACH TO THE HEAD TRAUMA PATIENT

Matthew W. Beal, DVM, Diplomate ACVECC
College of Veterinary Medicine
Michigan State University, East Lansing, MI

PATHOPHYSIOLOGY OF HEAD TRAUMA

Traumatic brain injury (TBI) in the small animal patient may occur subsequent to a number of traumatic events including, but not limited to human–animal interactions, motor vehicle accidents, projectiles, animal–animal interactions, and falls from a height. Primary injuries result from a variety of forces (acceleration, deceleration, torsion, etc.) imparted upon the cranium and its contents and may range from mass lesions caused by vascular disruption (epidural hematoma, subdural hematoma, intraparenchymal hemorrhage) to contusions and diffuse axonal injury. Excluding the surgical management of mass lesions (hemorrhage) and depressed skull fractures, there is little that we as veterinarians can do about the primary injury. However, minimizing the incidence or impact of secondary brain injury is the focus of the emergency medical management of the small animal TBI patient. Secondary brain injury refers to a variety of pathophysiologic processes that culminate in progressive neuronal damage at sites both local to and distant from the primary injury. These include, but are not limited to:

- **Decreased ATP:** Massive depolarization occurs after head trauma. Restoration of electrical gradients is dependent on adequate ATP levels. ATP will be depleted in association with this process. Failure of ATP-dependent membrane pumps can result in increased intracellular calcium (see below) as well as cellular edema and thus increased intracranial pressure (ICP).
- **Decreased Global Oxygen Delivery (DO_2):** Oxygen delivery to any tissue in the body is dependent on blood flow (Cardiac Output [CO]) and oxygen content of the arterial blood (C_aO_2). Cardiac output is equal to the product of stroke volume and heart rate. Stroke volume can be depleted in the trauma patient secondary to blood loss, restricted fluid administration, and the administration of diuretics. C_aO_2 is largely determined by [Hgb] and oxygen saturation. C_aO_2 can be depleted through alterations in blood hemoglobin concentration (hemorrhage) and oxygen saturation (pulmonary contusion, pleural space diseases, etc). Insufficient oxygen delivery to neuronal tissue will accentuate the already depleted ATP levels and predispose to the accumulation of lactic acid through anaerobic glycolysis. Aggressive resuscitation of the trauma patient will minimize the occurrence of secondary brain injury from decreased DO_2 (see below)
- **Excitotoxicity:** Glutamate is an excitatory neurotransmitter. After trauma, glutamate concentrations in the extracellular fluid increase resulting in an increase in intracellular calcium concentration. Elevated intracellular calcium concentrations then result in direct and indirect neuronal cell injury.
- **Other Mediators:** NO, complement, kinin, and coagulation/fibrinolytic processes.
- **Systemic Metabolic Disturbances:** Hypoglycemia will result in a decrease in the amount of substrate for ATP production.
- **Altered Vascular Reactivity (loss of autoregulation):** Autoregulation of blood flow occurs clinically on many levels and is responsible for the maintenance of appropriate blood flow to the brain across a variety of physiologic alterations. Pressure autoregulation refers to the ability of the cerebral vasculature to maintain cerebral blood flow across a variety of blood pressures (between a mean of 50–150 mmHg). Below 50 mmHg, cerebral blood flow falls, and above 150 mmHg, cerebral blood flow increases. After trauma, pressure autoregulation can be lost globally or locally resulting in a linear relationship between mean arterial pressure (MAP) and cerebral blood flow and the possibility that despite a normal MAP, cerebral blood flow may be inadequate. Metabolic/Chemical Autoregulation refers to the ability of the cerebral vasculature to regulate blood flow both locally and globally in response to changing metabolic activity of the neurons. Increased metabolic activity stimulates an increase in blood flow regionally (vasodilation), while decreased metabolic activity causes decreased regional blood flow (vasoconstriction). Carbon dioxide concentration also influences cerebral blood flow through its effect on the vasculature. Increased carbon dioxide levels result in vasodilation and decreased carbon dioxide levels can result in vasoconstriction. TBI can result in alterations in these autoregulatory processes resulting in inappropriate degrees of vasodilation or vasoconstriction with consequential inappropriate alterations in regional or global cerebral blood flow. Inappropriate vasoconstriction may result in decreased oxygen delivery to regional neurons while inappropriate vasodilation may result in increased intracranial pressure (ICP). Severe increases in ICP result in decreased cerebral blood flow (CBF). Decreased CBF results in increased CO_2 locally that is detected at the vasomotor center. The vasomotor center instigates a massive response from the sympathetic nervous system resulting in a dramatic elevation in MAP in an effort to increase cerebral perfusion pressure (CPP).

$$CPP = MAP - ICP$$

Increased MAP is detected at the baroreceptor and will often result in a reflex bradycardia. This reflex is called the ischemic response/Cushing reflex: The ischemic response occurs late and requires an intact vasomotor center to occur. Observation of the ischemic response should prompt the clinician to aggressively treat increased ICP (see below).

- The different mechanisms of secondary brain injury culminate in ongoing cellular injury and increased intracranial pressure.

CLINICAL APPROACH TO THE HEAD TRAUMA PATIENT

The approach to the small animal TBI patient should initially address the three major body systems (cardiovascular, respiratory, and CNS) in an effort to identify and institute treatment for immediately life threatening problems. Treatment for problems identified based on the examination of the cardiovascular and respiratory systems should be instituted immediately such that delivery of oxygen to the brain can be maximized. A rapid history including the time of the trauma, clinical signs immediately after the trauma and progression of those signs, medications administered, and previous pertinent medical history should be sought out soon after presentation.

Clinical manifestations and physical and neurologic examination findings in the small animal patient that has suffered TBI may include an altered level of consciousness, seizures, ataxia, proprioceptive deficits, and various cranial nerve deficits. The veterinarian may observe obvious wounds to the head and/or neck region, episcleral hemorrhage, hyphema, epistaxis, oral trauma (broken teeth, jaw), blood in the ears, and fractures on palpation of the bones of the head. Identification of any of the aforementioned injuries should prompt the clinician to consider the possibility of a significant intracranial injury and further diagnostic options. Immobilization of the TBI patient is important due to the possibility of concurrent spinal injury.

A resurgence of attention is being paid to grading the severity of TBI according to the Modified Glasgow Coma Score (MGCS). The MGCS was developed in 1983 by Shores in an effort to grade the severity of neurologic injury, allow for comparison to that baseline over time, and finally to predict prognosis. The scale was proposed as shown in Table 1.

A score is given in each of the categories above and then the scores are totaled. It has been proposed that a score of 3 to 8 suggests a grave prognosis, 9 to 14 suggests a guarded prognosis, and 15 to 18 suggests a good prognosis.[5] Retrospective evaluation of a series of 38 dogs with head trauma correlated the probability of survival within the first 48 hours with MGCS. A prospective evaluation of 24 dogs with head trauma showed that MGCS predicted length of stay, cost of care, and thus severity of injury but concluded that further studies will be necessary to determine if MGCS is a good predictor of outcome. Future studies will also be necessary to determine if MGCS will be a useful predictor of the necessity for CT scan after head trauma in dogs.

Table 1. Modified Glasgow Coma Scale

	Score
A. Motor Activity	
Normal gait, normal spinal reflexes	6
Hemiparesis, tetraparesis, or decerebrate activity	5
Recumbent, intermittent extensor rigidity	4
Recumbent, constant extensor rigidity	3
Recumbent, constant extensor rigidity with opisthotonus	2
Recumbent, hypotonia of muscles, depressed or absent spinal reflexes	1
B. Brainstem Reflexes	
Normal pupillary light reflexes and oculocephalic reflexes	6
Slow pupillary light reflexes and normal to reduced oculocephalic reflexes	5
Bilateral unresponsive meiosis with normal to reduced oculocephalic reflexes	4
Pinpoint pupils with reduced to absent oculocephalic reflexes	3
Unilateral, unresponsive mydriasis with reduced to absent oculocephalic reflexes	2
Bilateral, unresponsive mydriasis with reduced to absent oculocephalic reflexes	1
C. Level of Consciousness	
Occasional periods of alertness and responsive to environment	6
Depression or delirium, capable of responding but response may be inappropriate	5
Semicomatose, responsive to visual stimuli	4
Semicomatose, responsive to auditory stimuli	3
Semicomatose, responsive only to repeated noxious stimuli	2
Comatose, unresponsive to repeated noxious stimuli	1
MGCS = A+B+C	

Imaging studies (CT or MRI) of the intracranial structures should be considered in any patient with focal neurologic signs, moderate to severe neurologic signs of TBI on presentation, failure of clinical signs to improve within hours of initiation of treatment, or deterioration in clinical signs. Imaging will allow the clinician to rule in or out a significant mass lesion (epidural, subdural, or intraparenchymal hemorrhage) or depressed skull fractures as contributory to the clinical signs. Mass lesions and depressed skull fractures in patients with moderate to severe trauma and static or progressive clinical signs should be approached surgically. Imaging studies will also allow the clinician a better appreciation for the other injuries (contusion, edema) often present in the head trauma patient.

TREATMENT OF THE HEAD TRAUMA PATIENT

The following will discuss the pros, cons, indications, and contraindications for the various treatment options for the veterinary patient with TBI. Until controlled, prospective studies can be performed in clinical small animal patients with naturally occurring TBI, medical treatment recommendations for small animals must be made based on knowledge gained through human medical research as well as experimental models of head trauma in animals. The limitations of cross-species application of these recommendations must also be noted.

- **Fluid Therapy:** Fluid therapy for the dog or cat that has sustained TBI should be directed towards rapid restoration of intravascular volume and support of CPP through support of MAP. Bouts of hypoxemia or hypotension have been implicated as predictors of poor neurologic outcome in human patients that have suffered head trauma. Fluid therapy should never be restricted in the head trauma patient as dehydration will only result in slight decreases in ICP. At the same time, fluid restriction may jeopardize the MAP and thus CPP. Options for fluid resuscitation of the head trauma patient include isotonic crystalloid fluids, hypertonic saline, synthetic colloids, and blood or blood products.

  Isotonic crystalloid solutions (Normosol-R, 0.9% Saline) are reasonable resuscitation fluids for the patient that has sustained TBI. If isotonic crystalloid solutions are chosen for resuscitation, only that volume necessary to restore euvolemia, provide maintenance, and balance out ongoing losses should be administered.

  Hypertonic Saline resuscitation has the advantages of smaller volume resuscitation, rapid restoration of intravascular volume thus improving CPP, improved contractility, and its osmotic effect at the level of the brain thus lowering ICP. Disadvantages include perpetuation of hypernatremia and the pulmonary vagal reflex that can result in bradycardia during administration. There is some evidence that hypertonic saline may disrupt the blood brain barrier and thus nullify some of its beneficial effects. Hypertonic saline may be administered at a dose of 4 mL/kg of a 7.5% solution by slow IV infusion over 10 to 20 minutes. Diligent monitoring of serum sodium concentration is critical after administration especially with concurrent administration of other hypertonics such as mannitol. The effects of hypertonic saline may be short lived, but may be extended by concurrent administration of a synthetic colloid. Concurrent isotonic crystalloid administration for maintenance purposes and provision for ongoing losses will be required.

  Colloid solutions are considered by some to be the resuscitation fluid of choice in the patient that has sustained TBI. Benefits include a smaller volume necessary for resuscitation (when compared to crystalloid solutions), persistence in the vascular system and thus support of CPP, potential for minimizing vascular leakage, and prolonging the intravascular effects of hypertonic solutions. Hetastarch (6%) (5–10 mL/kg IV) is probably the most readily available colloid for resuscitation of the canine patient with TBI. In cats, the bolus (2.5–5 mL/kg) must be given over 20 to 30 minutes.

  Blood products are a very desirable resuscitation fluid in the patient with concurrent injuries resulting in hemorrhage and hypovolemia. Packed red blood cells, fresh whole blood, and fresh frozen plasma are all acceptable options. The use of hemoglobin-based oxygen carriers (HBOCs) in head trauma requires further investigation.

  Endpoints of fluid resuscitation include normalization of lactic acidosis and base-excess, return of normal or slightly increased arterial blood pressure, physical examination parameters consistent with resuscitation (pink mucous membranes, normal capillary refill time, normal heart-rate, strong pulses), and normal urine output.
- **Glucocorticoids:** The question of glucocorticoid usage is always up for debate with regard to utility in the management of TBI. Examination of the literature finds no consistent advantage to the utilization of glucocorticoids in head injured patients and potentially some disadvantages. According to the Brain Trauma Foundation, "The use of glucocorticoids is not recommended for improving outcome or reducing intracranial pressure (ICP) in patients with severe head injury."
- **Mannitol:** Mannitol is a sugar with a strong osmotic effect that has been shown to decrease both ICP and cerebral edema after traumatic brain injury. Mannitol exerts its advantageous effects through intravascular volume expansion, reflex cerebral vasoconstriction (decreased CBV) secondary to decreased blood viscosity, osmotic effects, and possibly through its free-radical scavenging effects. Undesirable effects of mannitol include its diuretic effect that could predispose to decreases in intravascular volume and subsequent decreases in DO_2 to the brain. Free water losses at the kidney may also result in hypernatremia after mannitol therapy. Close monitoring of electrolytes (primarily

sodium) is critical to the management of patients who have received mannitol. Dosage ranges from 0.25–1 g/kg IV. Intermittent bolus therapy may be superior to CRI and may avoid the reverse osmotic shift phenomena in which brain concentrations of mannitol exceed blood concentrations thus perpetuating cerebral edema. As a general guideline, no more than three doses of mannitol should be administered within a 24-hour period.

- **Hyperventilation in Head Trauma:** Hyperventilation (decreased P_aCO_2) results in decreased ICP through vasoconstriction of cerebral vasculature. Vasoconstriction, however, will result in decreased cerebral blood flow and thus decreased oxygen delivery to neurons (cerebral ischemia). Prolonged hyperventilation has been associated with inferior neurologic outcomes in people with severe injury when compared to those in which hyperventilation was avoided. Hyperventilation is only recommended as an emergency and transient effort to lower ICP. TBI patients undergoing anesthesia for diagnostic or therapeutic procedures should have P_aCO_2 kept in the 35 mmHg range. The advantage of positive pressure ventilatory support is that both oxygenation and ventilation can be controlled and episodes of desaturation of hemoglobin can be minimized.
- **Elevation of the Head:** Placing the patient on a board such that the head is approximately 15 to 20 degrees above the pelvis may improve cerebral venous drainage. Excessive elevation may decrease CPP and elevation of just the head may result in compression of the jugular veins and thus decreased venous drainage (and secondarily increased ICP). Jugular vein phlebotomy and catheterization is avoided for similar purposes (decreased venous drainage).
- **Oxygen Therapy:** Oxygen therapy should me administered to maximize oxygen saturation of hemoglobin as measured by pulse oximetry at the bedside. When providing oxygen to the head trauma patient, we should strive to make oxygen saturation approach 99%. Oxygen can be administered by cage, mask, hood, nasal cannulae, or transtracheal delivery methods. Those methods that cause coughing or sneezing should be avoided if at all possible as these effects may transiently increase ICP. If oxygenation cannot be maintained without F_iO_2 > 0.6 (60%), positive pressure ventilation is indicated.
- **Seizure Prophylaxis:** The incidence of early and late post-traumatic seizures in the veterinary head trauma patient is currently unknown. At the present time, in human medicine, routine seizure prophylaxis for late onset seizures is not a standard recommendation. Anticonvulsants are recommended for early posttraumatic seizures.[10] In veterinary medicine, benzodiazepines (for the actively seizing patient) and barbiturates (phenobarbital) are the most readily available drugs for this purpose. The author utilizes phenobarbital for seizure prophylaxis in patients that have demonstrated seizures in the early post-traumatic period. Treatment is continued for a minimum of 2 months.
- **Sedation/anesthesia in the small animal with TBI:** Cardiovascular and respiratory sparing sedation protocols are optimal in TBI (oxybarbiturates, opioid/benzodiazepine combinations). $ETCO_2$ and oxygen saturation (SpO_2) should be monitored to avoid episodes of hypoventilation and hypoxemia. Blood pressure should be monitored closely and hypotension should be avoided. Ketamine is not recommended due to increases in ICP that result after administration.

MONITORING THE TBI PATIENT

Monitoring of the veterinary TBI patient should focus on the three major body systems. Blood pressure (oscillometric, Doppler, or direct arterial blood pressure) should be monitored every 1 to 2 hours or more frequently as deemed necessary. Systolic blood pressure should ALWAYS be greater than 120 mmHg recognizing that in the absence of pressure autoregulation, cerebral blood flow may be reduced even at this pressure. A goal of MAP 80 to 120 mmHg is reasonable. ECG monitoring on a continuous basis is excellent for assessment of heart rate and rhythm. Bradycardia may be a sign of severe increases in ICP. Continuous pulse oximetry allows the veterinarian to monitor for bouts of arterial desaturation (a common cause of secondary brain injury). SpO_2 should approach 99%. Arterial blood gas analysis and/or end-tidal capnography will allow the clinician to assess P_aCO_2 levels and possibly avoid bouts of hypoventilation (>40 mmHg). Much of the monitoring equipment available today has functions for preset alarms. Utilization of these alarms to sound upon desaturation, bradycardia, hypotension, etc. is useful. If mannitol or hypertonic saline are being utilized, frequent assessment of electrolytes (at least twice daily) is critical to avoid hypernatremia or a host of other electrolyte abnormalities. Electrolytes, acid/base status, and blood glucose should always be assessed at least once daily in the critically ill patient and fluid therapy adjusted to maintain electrolytes within normal limits. Normalization of blood glucose may be beneficial to the patient that has suffered head trauma. Measurement of urine output via urethral catheterization will facilitate calculation of fluid ins-and-outs such that fluid therapy can be tailored to help maintain euvolemia and hydration. Frequent neurologic examinations focused on MGCS can help identify both progressive intracranial conditions and clinical improvement. Any negative changes in physiologic parameters or physical exam parameters should instigate rapid diagnostic and therapeutic responses on the part of the clinician.

CONCLUSION

Traumatic brain injury is a common occurrence in the polytrauma patient. Attention must first be paid to immediately life threatening processes and then directed towards support of major injuries. Thorough physical examination followed by appropriate diagnostic testing and therapeutic strategies will maximize the likelihood of a positive outcome.

TRANSFUSION MEDICINE FOR THE GENERAL PRACTITIONER

Matthew W. Beal, DVM, Diplomate ACVECC
College of Veterinary Medicine
Michigan State University, East Lansing, MI

SELECTING CANINE AND FELINE BLOOD DONORS BASED ON TYPE

Dog Erythrocyte Antigens (DEA) are glycolipids and glycoproteins on the surface of the red blood cell. The presence or absence of these DEA defines the blood type of an individual. Currently, it is believed that greater than 13 DEA exist. Of these, 8 are considered international standards (DEA 1.1, 1.2, 3, 4, 5, 6, 7, 8) and antisera (for typing) exist to six of them (DEA 1.1, 1.2, 3, 4, 5, 7). It is also possible to type for DEA 1.3. The blood type of the "universal" canine blood donor varies dramatically based on individual theory, laboratory investigation, clinical experience, or a combination of these. There are two "poles" of the universal donor typing debate.

At one end of the spectrum, is the philosophy that the universal donor is one that is positive for DEA 4 (as are 98% of the population) and negative for all other DEA for which antisera (for typing) exist and negative for all anti-DEA antibody (Ab). This approach to selecting the "universal" canine donor is most likely to minimize the likelihood of an acute hemolytic transfusion reaction, maximize the lifespan of the transfused blood and make future cross match most likely to be compatible with the recipient.

At the other end of the spectrum is the theory that because DEA 1.1 is the DEA clinically implicated most often as a cause of acute transfusion reaction in previously sensitized dogs, this is the only DEA that we must routinely type for. This approach to selecting the "universal" canine blood donor will maximize the size of the donor pool.

Practical Recommendations for Selecting Canine Donors Based on Type

- Type potential canine donor dogs with card test as DEA 1.1(+) or 1.1(-)
- Only consider using DEA 1.1(-) donors OR use DEA 1.1(+) donors for DEA 1.1(+) recipients and DEA 1.1(-) donors for DEA 1.1(-) or 1.1(+) recipients
- Proceed to further screening (see below)

Selection of feline blood donors based on blood type is much more straightforward than the canine system. Cats have three possible blood types: A, B, and AB. In the Northeastern United States, Type A cats account for approximately 99.7% of the feline population while Type B accounts for approximately 0.3% of the population. Type AB is extremely rare. Twenty to 45% of Exotic and British Shorthair Cats, Cornish and Devon Rex and 11-20% of Abyssinian, Barman, Persian, Somali, Sphinx, and Scottish Fold are type B. Unlike dogs, cats possess strong naturally occurring antibody to the opposite blood type. Consequently, inappropriate transfusion of Type A blood into a Type B cat will result in death. Transfusion of Type B blood into a Type A cat will result in an acute hemolytic transfusion reaction, but will probably not be fatal. To further illustrate the importance of feline blood typing, we can examine the phenomena of neonatal isoerythrolysis. Type A kittens born to a Type B queen will receive strong anti-A antibody in the colostrum resulting in life threatening hemolysis. Feline blood typing is available through commercial laboratories or via an available card test.[a,b] More recently, a new feline erythrocyte antigen designated *Mik* has been identified to which naturally occurring antibody also appears to exist in *Mik* (-) cats. *Mik* (-) cats may develop acute hemolytic transfusion reactions after being transfused with *Mik* (+) but AB compatible blood. It appears that a majority of cats are *Mik* (+).

Practical Recommendations for Selecting Feline Donors Based on Type

- Type potential feline donors as Type A or B. Try to identify a donor of each type to be available for donation.
- Only consider using Type A blood for Type A cats and only consider using Type B blood for Type B cats
- When transfusion is urgent, transfuse with type specific blood.
- When transfusion is elective, crossmatch to identify
- Proceed to further screening (see below)

SELECTING CANINE AND FELINE BLOOD DONORS (FACTORS OTHER THAN TYPE)

Numerous selection factors other than blood type are critical to ensuring the safety of canine and feline blood transfusions. Screening for these factors can be somewhat time-consuming and costly; however, if it prevents morbidity or mortality to the donor or the recipient, then the increased effort is well worth the added time and expense.

After we have identified dogs with suitable blood type for donation (see above), in the Northeastern United States, we must screen for infectious diseases[6] including *Ehrlichia canis* (IFA), *Babesia canis* and *B. gibsonii* (PCR), *Mycoplasma haemocanis* (*Haemobartonella* sp) (PCR), *Ehrlichia* genus (PCR), *Leishmania* (IFA), and heartworm disease (*Dirofilaria immitis*) (Ag). Appropriate donors should have negative antibody titers to *Ehrlichia canis* and *Leishmania* spp, negative *Babesia* spp PCR, negative *Mycoplasma haemocanis* PCR, and negative *Ehrlichia* genus PCR, as well as a negative heartworm antigen test (concurrently receiving preventative).[c] Recent concern regarding the blood-borne transmission of leishmaniasis to a number of patients at a veterinary teaching hospital has prompted the recommendation to avoid using Foxhounds for donation and to consider random testing of the general donor population. Additional infectious disease testing that may be recommended includes *Brucella canis* (RAST), *Bartonella vinsonii* (IFA), and *Trypanosoma* spp (IFA). In addition to being free from infectious disease, potential donors should be less than 8 years of age, have a normal complete blood count (CBC), serum biochemical profile, and urinalysis, no previous medical problems, a body weight greater than 40 pounds, no concurrent medications, an appropriate vaccination history, no previous transfusion history, and a personality that will allow for sustained restraint for blood collection. The author currently also evaluates donors for von Willebrand Factor levels. All screening with the exception of blood type and von Willebrand factor level should be repeated on an annual basis.

Additional screening (beyond blood type) for feline blood donors in the Northeastern United States is similar to that utilized in dogs. Infectious disease screening should evaluate potential donors for FeLV (Ag), FIV (Ab), *Mycoplasma haemofelis* and *haemominutum* (PCR), and *Bartonella* spp (PCR). Due to the behavior of FeLV and the immune response to it, the author currently screens cats initially for FeLV using an antigen test, followed by a second test after 3 months of complete isolation from other cats. Suitable donors should be FeLV negative, FIV negative, and have negative PCR for *Mycoplasma* spp. Donor cats should weigh greater than 10 lbs, have normal CBC, serum biochemical profile, and urinalysis, no previous medical problems, no current medications, a good vaccination record, no previous transfusions, and a personality conducive to phlebotomy. Many cats require sedation for blood donation purposes. Regarding environment, donor cats must not have any contact with other unscreened cats, must NEVER go outside, must NEVER have contact with screened cats that go outside, and must be re-screened on a yearly basis. Generally, it is most convenient for donor cats to live in the clinic/hospital where their environment can be well controlled (avoiding other cats). Finally, due to the significant incidence of occult cardiomyopathy in the feline population, the author recommends echocardiographic assessment of donor cats annually as a "donor-safety" factor.

COLLECTION OF BLOOD FOR TRANSFUSION

Prior to blood collection, all canine and feline donors should be weighed, examined, and have a small blood sample drawn for PCV or Hgb determination. If sedation is necessary, the author routinely uses an opioid in dogs (hydromorphone[d] or butorphanol[e]) and ketamine/ midazolam IV or isoflurane[f] by mask in cats.

The area over the jugular vein should be clipped and a surgical preparation performed. For dogs, we routinely use a commercially available closed collection system containing CPDA-1 anticoagulant.[g] CPDA-1 consists of citrate for anticoagulation and phosphate, dextrose, and adenine as precursors for ATP production. Collection in cats is generally performed using an open system consisting of syringe(s) with a 1 mL CPDA-1 per 9 mL of blood and a 19-gauge butterfly catheter. Risks of bacterial contamination using an open system are significantly greater than those with a closed system. From 400 to 450 mL of whole blood may be collected from dogs and 40 to 50 mL of whole blood may be collected from cats. On rare occasion, cats and dogs may show signs of hypovolemia after donation requiring rapid intravascular volume expansion with IV fluids. If this happens, donation protocol may need to be adjusted. Whole blood should be used immediately if an open collection system was used. To retain clotting factor function, whole blood should be used or processed into components within 8 hours of donation. Whole blood and packed red blood cells collected into CPDA-1 from a closed collection system can be stored in a strictly temperature controlled refrigerator at 4°C for up to 35 days with the addition of additive solutions[h] to improve RBC viability. The blood bags should be turned daily.

BLOOD PRODUCT ADMINISTRATION:

Most transfusions in veterinary medicine are performed electively; however, in emergency situations like hemorrhagic shock, blood and blood products can be administered as rapidly as is necessary (using a pressure delivery system). Blood and blood products should ALWAYS be delivered via a commercially available 170 µm blood filter.[i] A filter with low dead space is best used in cats and small dogs receiving less than 60 mL of blood or blood product.[j] Filtration of the blood will eliminate blood clots and other large particles that could cause embolic disease in the recipient. Elective transfusion of whole blood or packed red blood cells should begin slowly (1–3 mL over 5 min in cats and 0.25 mL/kg over the first 30 min in dogs) while monitoring for signs of transfusion reaction (see below). If no reaction is noted, the transfusion may be delivered over 1 to 4 hours while intermittently evaluating for any evidence of a transfusion reaction. Recipients with underlying heart disease or other conditions that may predispose to hypervolemia should receive their transfusion slowly to avoid volume overload. Whole blood or blood products should NEVER be infused over a period of time longer than 4 hours due to the risk of bacterial proliferation within the product.

TRANSFUSION REACTIONS

Acute immunologic transfusion reaction may occur when antibodies to donor RBCs are present in the recipient plasma. An example would be the administration of Type A blood to a type B cat (you will remember that all type B cats have potent anti-A antibody). In this clinical situation, the donated cells would be rapidly destroyed in 1 to 2 hours and the recipient would likely die. A similar situation would occur if a DEA 1.1 negative dog is transfused twice (more than 3 to 5 days apart) with DEA 1.1 (+) blood. Antibody to DEA 1.1 in the plasma of the recipient would cause the rapid hemolysis of the transfused RBCs. Other less severe signs of acute immunologic transfusion reactions include fever and urticaria. Life-threatening acute immunologic transfusion reactions can be avoided in most cases by the administration of type specific blood and performing major and minor cross match when indicated. Examples of acute non-immunologic transfusion reactions may include air embolism, blood clot embolism, hypocalcemia because of citrate (anticoagulant used in blood collection) toxicity, and bacterial contamination of the product, causing septicemia in the recipient. Delayed immunologic transfusion reactions result from development of antibody that could shorten transfused RBC lifespan. Delayed non-immunologic transfusion reactions could result from the transfusion of blood contaminated with organisms like FeLV or FIV. Delayed non-immunologic reactions can be prevented through appropriate donor screening.

PLACEMENT OF CENTRAL VENOUS CATHETERS: SELDINGER TECHNIQUE

Matthew W. Beal, DVM, Diplomate ACVECC
College of Veterinary Medicine
Michigan State University, East Lansing, MI

Vascular access serves as the lifeline to critically ill small animal patients, allowing for delivery of life-saving fluids, blood products, and drugs while simultaneously guiding the resuscitation effort by providing data on arterial and venous pressures.

USES AND INDICATIONS

By definition, the tip of a central venous catheter (CVC) terminates in the cranial or caudal vena cava. Most CVCs are placed in the cranial vena cava via the jugular vein; however, peripherally inserted central catheters (PICCs) may be placed into the central circulation via a peripheral vein. Central venous catheters have many advantages over the more widely used over-the-needle peripheral venous catheters, including the ability to monitor CVP; infuse hyperosmolar or irritant solutions, such as total parenteral nutrition; and reliably and atraumatically retrieve diagnostic blood samples, as is often necessary in critically ill or diabetic patients.

To monitor CVP, the tip of the CVC should terminate in the thoracic vena cava of dogs and the thoracic or abdominal vena cava of cats. Many CVCs have multiple lumens, allowing delivery of several incompatible solutions concurrently or facilitating monitoring of CVP while several types of fluids are being administered. The author considers the multilumen CVC a key tool that facilitates both monitoring and management of critically ill dogs and cats.

CONTRAINDICATIONS AND PRECAUTIONS

General contraindications to placement of a CVC via the jugular, maxillary, or femoral vein include presence of a significant hemostatic abnormality, such as severe thrombocytopenia (<20,000/μL); known severe thrombocytopathia; coagulopathy; or overt bleeding tendencies. They are also contraindicated in patients with disease processes suspected to be associated with hypercoagulable states, such as immune-mediated hemolytic anemia or protein-losing nephropathy, because of concerns about cranial vena cava thrombosis and pulmonary thromboembolism. A CVC placed in the jugular or maxillary veins are also contraindicated in patients with traumatic brain injury because of the potential decrease in cerebral venous drainage that may occur during manipulation of the veins of the neck. Most CVCs tend to be long in length and relatively narrow in diameter, making rapid infusion of large amounts of fluid or blood products difficult.

EQUIPMENT

Central venous catheters come in many varieties, including over-the-needle catheters, through-the-needle catheters, and those placed using the Seldinger technique. Over-the-needle catheters tend to be stiff and prone to kinking when used as CVCs, whereas through-the-needle catheters are usually the single-lumen variety, which create a vascular defect slightly larger than the catheter itself. Many through-the-needle catheters are difficult to secure. The Seldinger technique facilitates cannulation of a vascular structure using a small-gauge catheter or needle, allowing introduction of a flexible guidewire and subsequently a catheter. It has also been used to catheterize other vascular structures and the peritoneal, pleural, and pericardial cavities.

CATHETER SELECTION AND PREPARATION FOR JUGULAR VEIN PLACEMENT

The length should be such that the tip of the catheter lies within the thoracic vena cava at approximately the level of the 2nd rib space. Measuring the distance between the middle of the jugular vein to the 2nd rib space helps in selecting a catheter of appropriate length. The author generally chooses 4-French catheters for very small dogs and cats (< 7 lb), 5.5-French catheters for animals between 7 and 25 pounds, and 7-French catheters for animals heavier than 25 pounds. All lumens of the CVC, and the over-the-needle catheter or introduction needle, should be filled with heparinized 0.9% saline (1 U/mL).

HOW TO PLACE A CENTRAL VENOUS CATHETER (SELDINGER TECHNIQUE)

Note: The following step-by-step procedure discusses placement of a two-lumen, 7-French, 20-cm CVC via the right jugular vein in a dog. In the following series of images, the patient is always positioned in left lateral recumbency and the head is always to the right of the image.

1. Position patient in lateral recumbency and clip from mid-mandible to second sternebra and dorsal midline to the opposite jugular vein (Figure 1). To assess appropriate field preparation, be sure that no hair from the unclipped area can be folded within 5 cm of the proposed insertion site. Prepare the clipped area using alternating chlorhexidine-based scrub solution and alcohol as for surgery. Use sterile gloves during catheter placement. Use of barrier gown and surgical mask further minimizes risk for contamination.

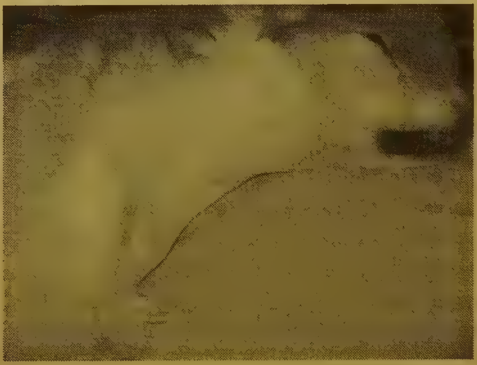

Figure 1.

2. The jugular vein lies between the caudal ramus of the mandible (identified by finger in image) and the thoracic inlet. Place an impermeable drape with a fenestration approximately 3 to 5 cm in diameter over the jugular vein, one third of the distance between the caudal ramus of the mandible and the thoracic inlet (Figure 2).

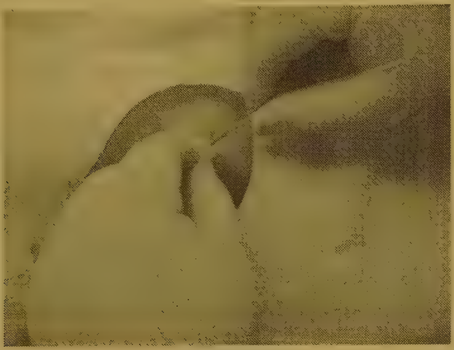

Figure 2.

3. An assistant should occlude the jugular vein at the thoracic inlet to identify its course. The assistant then releases pressure on the jugular vein, so you can tent the skin over the jugular vein and make a 3- to 4-mm incision in the skin using a No. 11 scalpel blade. Point the cutting edge of the blade away from the patient to minimize the risk for injuring underlying vasculature. This small defect eliminates tissue drag and is known as the percutaneous facilitative approach. This step is a variation on the original Seldinger technique, in which the skin incision is made after step 6 (Figure 3).

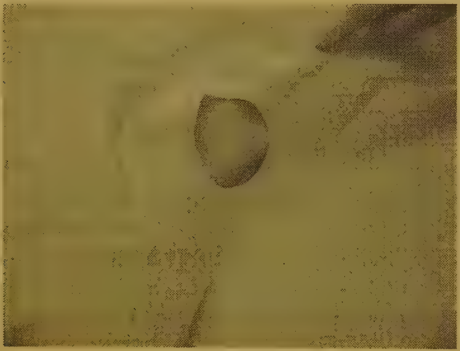

Figure 3.

4. Reocclude the jugular vein at the thoracic inlet and place an over-the-needle catheter (see Figure 5) or thin-walled introducer needle (see Figure 4) into the jugular vein. Most CVC kits contain both an over-the-needle catheter and an introducer needle of appropriate size to accommodate the J-tipped spring guidewire. Attach a syringe filled with heparinized 0.9% saline to the end of the introducer needle or over-the-needle catheter to minimize the risk for air embolus. Intermittent aspiration of this syringe during placement will signify that the jugular vein has been penetrated when a flash of blood is seen in the hub of the needle.

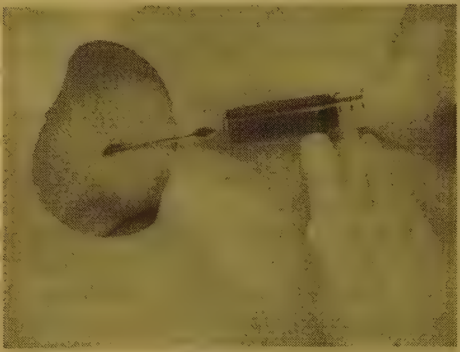

Figure 4.

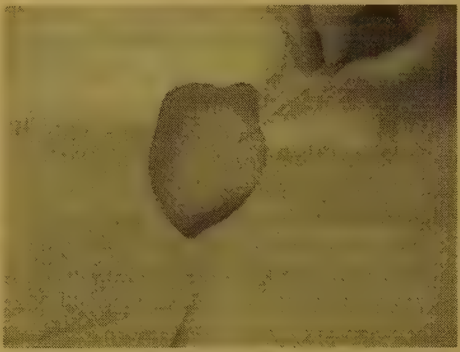

Figure 5.

5. Insert the J-tipped spring guidewire (Figure 6) into the introducer needle or over-the-needle catheter (Figure 7). When the wire passes out of the lumen of the introducer needle or over-the-needle catheter and into the jugular vein, the J-tip will activate, minimizing risk to the vasculature or the heart if the wire comes into contact with it. Note the length of the wire and be sure to advance it only to the level of the cranial vena cava (approximately the 2nd rib space).

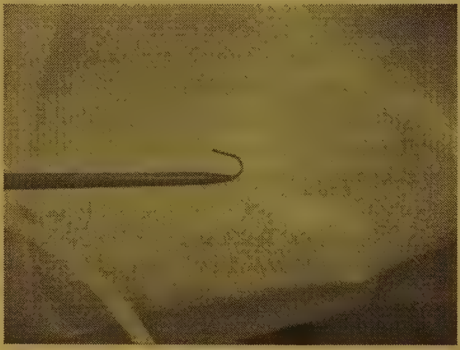

Figure 6.

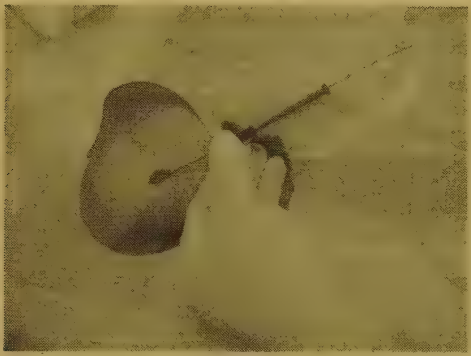

Figure 7.

6. Remove the introducer needle or over-the-needle catheter over the J-tipped spring guidewire. At this stage, only the J-tipped spring guidewire is left in the vessel (Figure 8).

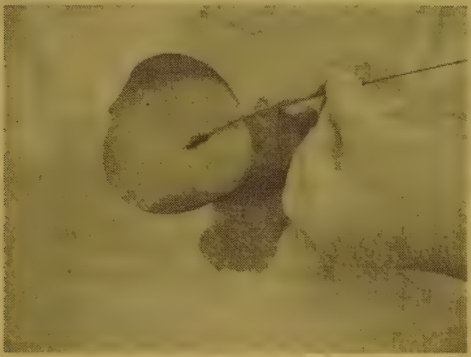

Figure 8.

7. Insert the vessel dilator (see Figure 9) over the J-tipped spring guidewire and into the jugular vein. (see Figure 10) The dilator creates a larger defect in the subcutaneous tissues, allowing the catheter to enter smoothly. Remove the dilator. At this stage, again only the J-tipped spring guidewire should be left in the vessel (as seen in Step 8). Some bleeding may be noted at this time. Apply mild direct pressure at the insertion site to mitigate hematoma formation.

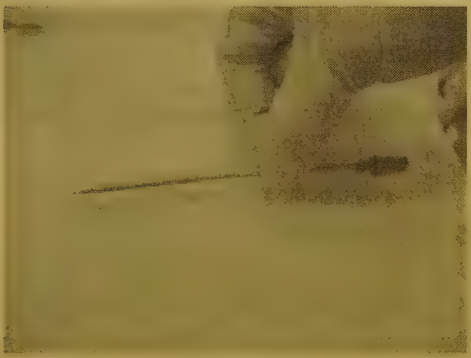

Figure 9

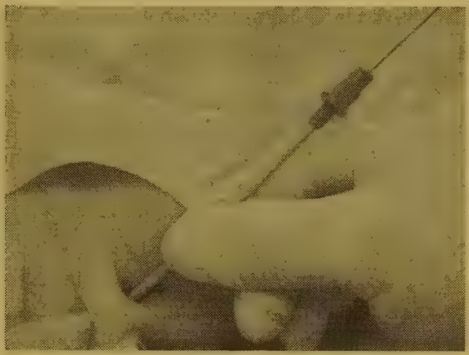

Figure 10.

8. Advance the catheter filled with heparinized 0.9% saline (see Figure 11) over the J-tipped spring guidewire (see Figure 12).

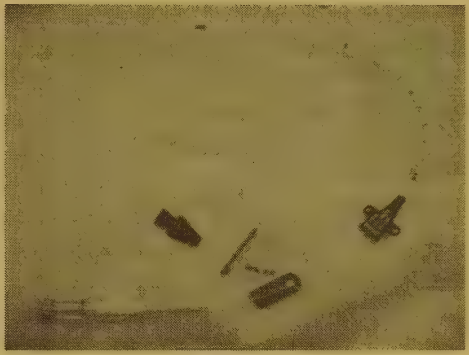

Figure 11.

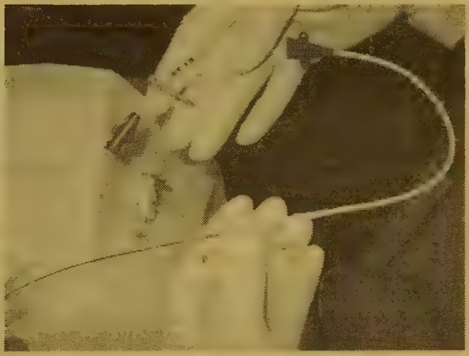

Figure 12.

9. Grasp the end of the J-tipped spring guidewire, which prevents loss of the wire within the patient, and then advance the catheter into the jugular vein. See Figure 13.

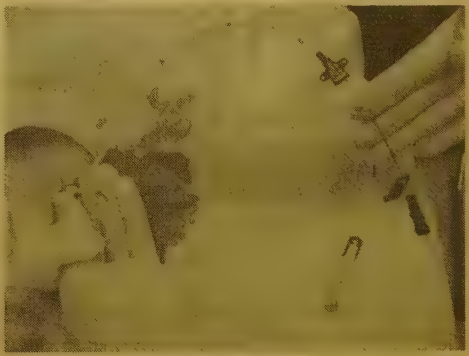

Figure 13.

10. Remove the J-tipped spring guidewire from the catheter, leaving the catheter within the jugular vein (Figure 14).

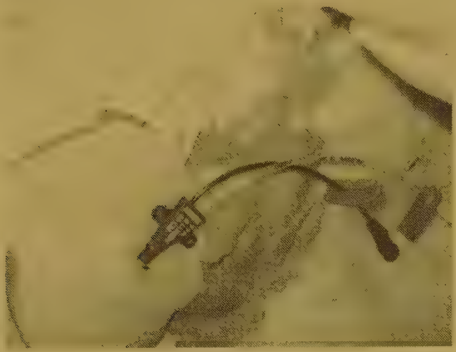

Figure 14.

11. Suture the catheter in place at three anchor points. The "collar" of the catheter should be sutured in line with the jugular vein (Figure 15).

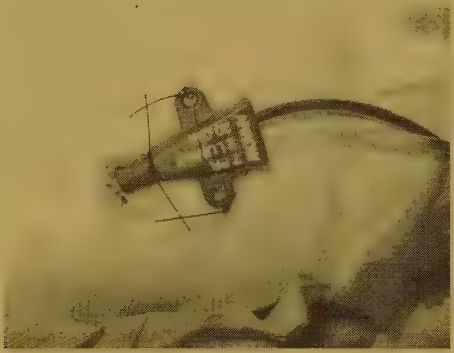

Figure 15.

12. Apply a sterile dressing to the insertion site. Evaluate the dressing and the site daily for redness, swelling, or discharge, and change the dressing daily. Most CVCs can remain in place for up to 1 to 2 weeks as long as no indications for removal exist (eg, redness, swelling, or discharge at the insertion site; cessation of ability to reliably sample from the catheter; jugular vein thrombosis) (Figure 16).

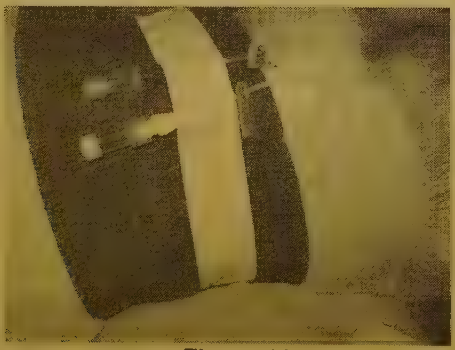

Figure 16.

13. Thoracic radiography may be used to assess the location of the tip of the catheter. (Note: This image is not from the same patient as in previous images but illustrates proper site of placement) (Figure 17).

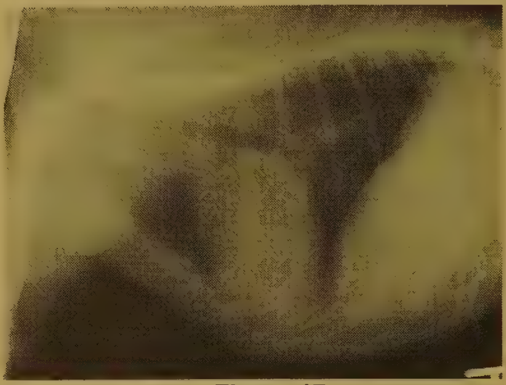

Figure 17.

If a fever or other signs of infection of unexplained origin develop, the catheter should be considered as a likely cause and removed and cultured.

WHAT YOU WILL NEED

- Materials to create a sterile field (clippers, antiseptic preparation solution)
- Drape (usually included with central venous catheter kit)
- Central venous catheter kit (most kits include all necessary materials for placement) (Arrow International; Reading, PA)
- Sterile gloves
- Barrier gown, towel, mask
- Heparinized 0.9% saline solution (1 U/mL)
- Bandages

PROCEDURE PEARLS

- The CVC allows the clinician to measure CVP, to infuse hyperosmolar or irritant solutions (such as total parenteral nutrition), and to reliably and atraumatically retrieve blood samples.
- The tip of the CVC placed for monitoring CVP should terminate in the thoracic vena cava of dogs and the thoracic or abdominal vena cava of cats.
- General contraindications to the placement of a CVC via the jugular, maxillary, or femoral vein include presence of a significant hemostatic abnormality.
- The multilumen CVC is a key tool that facilitates both monitoring and management of critically ill dogs and cats.

EVERY CLINIC IS AN EMERGENCY CLINIC: RAPID ASSESSMENT — "THE FIRST 15 MINUTES"

Tim Hackett, DVM, MS, Diplomate ACVECC
College of Veterinary Medicine
Colorado State University, Fort Collins, CO

Whether we like it or not, emergencies are a way of life for any practicing veterinarian. A client in their car racing for help is not going to understand "appointment only" or "practice limited to..." The client with an emergency will only understand "Veterinarian" and recognize the practice as a likely place to find help. Regardless of equipment, veterinarians, and there staff need to feel comfortable providing assistance for the emergency patient. This article focuses on basic triage procedures and skills needed in the first minutes of a patient's arrival to save the patients that have a chance at survival.

TRIAGE

The receptionist and veterinary technicians are the front line in any practice. As the first people a client speaks to or meets, they have the responsibility of quickly identifying life-threatening problems. If problems are severe the technical staff may have to initiate resuscitation while calling in the veterinarian.

Triage is a term describing the prioritizing of cases based on their need for emergency care. In busy practice it may mean juggling several critical patients simultaneously. Nursing care of the critically ill or injured animal is challenging due to the dynamic and often severe nature of the underlying diseases or injuries. Careful monitoring of clinical parameters is vital to the assessment and treatment of the patient. With focused attention to detail, deterioration of the patient's condition may be recognized early, allowing for administration of treatment and nursing care that ultimately reduces morbidity and mortality.

Veterinary technicians have the closest and most continuous contact with patients and therefore have the opportunity to recognize subtle changes. While sophisticated monitoring and treatment equipment is becoming increasingly available to veterinary practices, much can be accomplished by using one's senses, common sense and simple equipment.

TELEPHONE TRIAGE

When owners suspect a problem with their pets, their first impulse is usually to call your hospital for advice. When they call, they are concerned and are looking to you for suggestions. If the animal is showing ANY abnormal symptoms, the owner should be instructed to bring the animal to the hospital. It is impossible to completely triage a patient over the phone. Owners may be hoping you will tell them it is OK not to come in. For simple problems, this may be true, but for other problems, not recommending a hospital visit could be a big mistake.

Staff must cautious when recommending any treatment without seeing the animal. Any animal that is obtunded, depressed, seizing needs to be seen immediately. If your hospital is closing, they should be instructed to seek emergency care as recommended by your hospital (an on-call veterinarian or emergency center).

EMERGENCY ASSESSMENT

Any antidotal treatment is useless if vital organ function is lost. Regardless of the problem, an initial assessment must be made of cardiopulmonary function and appropriate actions must be taken early to treat any problems identified. Using an "ABC" approach to any sick animal will keep the emergency team focused on life-threatening problems:

Airway

Be sure the animal has a patent airway. A quick oral exam and finger sweep can remove any obstruction. Visually inspect the larynx for swelling or obstruction. If the animal is obtunded, protect the airway by intubating the animal with a low-pressure cuffed endotracheal tube.

Breathing

Is the animal breathing? Are the breaths of adequate rate and depth? Is oxygen getting from the lungs into the tissues? Observation, auscultation, and examination of the mucous membranes can answer these questions. If the mucous membranes are pale or cyanotic, supplemental oxygen should be provided immediately.

Circulation

Check pulse quality, heart rate and rhythm. If pulses feel week or irregular, and electrocardiogram should be evaluated. Patients in shock should have an intravenous catheter placed, blood samples drawn and fluids ready to administer. If the heart rate is rapid and the pulse quality weak, Shock volumes of crystalloid fluids may need to be given. The volume of fluid required is based on the patient's weight, but you should be prepared to administer a full blood volume each hour if crystalloid solutions are being used. In the dog this will be about 90 mL/kg/hr and for the cat about 44 mL/kg/hr.

A safer, more titrated approach to "shock fluids" would be to divide the total fluid volume into 1/4 volumes [(880 mL divided by 4 = 220 mL) or (900/4 = 225)] and then frequently monitoring, one may determine when it is appropriate to move to the second phase of fluid resuscitation (dehydration phase). If the clinical signs of shock resolve after the first 10 minutes, there is no need to proceed with another bolus of fluid. Move on to the dehydration phase.

One must be cautious about overhydration and hemodilution. Overhydration during the emergency phase is most likely to occur when large volumes are administered to animals with pulmonary contusions, pre-existing pulmonary edema, aspiration pneumonitis, hypoproteinemia, brain injuries, and congestive heart failure.

Reassessment is mandatory. Patients should be continually reevaluated and therapy changed as needed. With aggressive fluid therapy we should expect the heart rate to slow, the pulses to become stronger, and organ perfusion to improve. Clinically the color of the patient's gums should look more normal and the animal should act more alert. Packed cell volume and total solids should be rechecked after 25% to 50% of the total shock volume has been given. If the packed cell volume has dropped below 25% to 30% whole blood, packed red blood cells, or Oxyglobin may be needed. If the total solids drop below 3.5 g/dL or less than 50% of the starting value, consider a colloid such as plasma, hydroxyethyl starch or dextrans.

SUPPORTIVE CARE

Throughout the resuscitation, the patients should be continually monitored for adequate oxygenation and ventilation. Depressed, obtunded, debilitated patients should be turned at regular intervals to prevent pulmonary atelectasis and pressure sores. Closed urine collection system may be employed to assess urine output and prevent soiling. Changes in packed cell volume, and total serum solids may require blood transfusion or other colloid support. Once everything has been done to prevent absorption and hasten elimination of any poison, excellent nursing care will provide the patient time to heal from the toxic insult.

FLUID BALANCE

Frequently check the heart rate, body weight, packed cell volume, total solids, mentation and urine production are essential to determine fluid needs. With patients receiving large fluid volumes, thoracic auscultation should be repeated often, listening for changes associated with pulmonary edema. As technicians spend more time at the patients side, they should be listening to these patients frequently. Assess the response to fluid therapy, make changes if necessary, avoid overhydration and watch for early signs of organ dysfunction.

BLOOD PRESSURE/PERFUSION

Blood pressure can be easily measured indirectly although more invasive direct means are also available. Systolic blood pressure should be maintained above 90 mmHg with the goal being a mean arterial pressure above 70 mmHg. Mean pressures below 60 mmHg can lead to impaired perfusion of vital organs especially the kidneys. The hypotensive patient should be given volume (crystalloids and if indicated, colloids), supplemental oxygen and cardiac support with vasoactive drugs if volume alone can not restore blood pressure. Agents which can be used to improve blood pressure include dopamine, dobutamine and norepinephrine.

HEART RATE AND RHYTHM

Cardiac arrhythmias that compromise cardiac output should be treated appropriately. Supraventricular and ventricular tachycardias can impair ventricular filling and lead to a reduced cardiac output. Ventricular tachycardia with R on T phenomenon can lead to sudden death from ventricular fibrillation and should receive antiarrhythmic therapy immediately. Heart block can lead to functional bradycardia and reduced cardiac output. Because a patient with SIRS is at risk for any number of potentially harmful arrhythmias constant monitoring is important.

TOTAL SOLIDS, ALBUMIN AND ONCOTIC SUPPORT

In a healthy animal albumin provides most of the plasma oncotic pressure. Serum albumin should be monitored and kept above 2.0 g/dL using plasma or whole blood transfusions. Persistent hypoalbuminemia is associated with increased mortality in critically ill animals. When patient size and albumin deficit makes plasma transfusion alone impractical, any one of the synthetic colloidal solutions (hetastarch or dextrans) can bridge the gap and help maintain plasma oncotic pressure.

OXYGENATION AND VENTILATION

Oxygen delivery to the vital tissues is the goal of all resuscitative techniques. Oxygen supplementation (by face mask or an oxygen cage) is a simple emergency drug that can help organ function in critical patients. Since oxygen delivery is a function of arterial oxygen content and cardiac output positive changes in any of these variables can improve oxygen delivery. With fluids and cardioactive drugs supporting vascular volume and blood pressure cardiac output is maintained. When available, arterial blood gas analysis will identify abnormal oxygenation and ventilation. Without arterial blood gas, close attention to mucous membrane color and respiratory rate will give much of same information.

RED BLOOD CELL (HEMOGLOBIN) CONCENTRATION

Another variable in determining arterial oxygen content (and therefore oxygen delivery) is the red blood cell mass. The use of crystalloid fluids, plasma and synthetic colloids during resuscitation and rehydration can significantly hemodilute patients. Although the improvements in cardiac output are important, the use of whole blood or packed red blood cell transfusions should be used to maintain a hematocrit between 27% and 33%.

ACID–BASE BALANCE, GLUCOSE AND ELECTROLYTES

Calcium, sodium, chloride, magnesium, and potassium should be maintained within normal limits. Potassium should be added to maintenance fluids to avoid iatrogenic hypokalemia. Blood glucose should be maintained between 100 and 200 g/day. Drops in blood glucose or levels that are not above normal in the face of added dextrose can be seen in acute sepsis.

RENAL FUNCTION AND MENTATION

Urine output should be monitored continually. Inappropriately low urine output (< 1 mL/kg/hour) may represent acute renal failure and appropriate measures with fluids, diuretics and vasoactive drugs like dopamine should be considered. Monitor BUN and creatinine in these animals as another gauge of renal function.

Mentation is a subjective but important way to gauge neurologic dysfunction. Support of blood glucose, oncotic pressure and serum osmolality will decrease the risk of neurologic injury.

COAGULATION

Disseminated intravascular coagulation (DIC) is a common component of critical illness. Daily screening for evidence of DIC in patients at risk can help the clinician intervene. Examination of a blood smear for decreased platelets and fragmented red blood cells is inexpensive and easy. Activated clotting time is another excellent screening test for the intrinsic and common pathways of coagulation. More specific tests for fibrin degradation products (FDP's) and Antithrombin III (AT III) levels may help guide therapy. Therapy is directed toward decreasing microthrombi (heparin and AT III), providing missing factors (fresh frozen plasma) and improving perfusion.

NUTRITION AND IMMUNE STATUS

Even with appropriate antibiotics, the body must provide basic defenses to destroy and reverse the negative complication of critical illness. Patients with extremely low white blood cell counts may need antibiotics. Monitoring white blood cell count is an important gauge of host defense and response to systemic illness.

Malnutrition results in compromised host defenses. Lack of oral feeding can cause a loss of bowel integrity, leading to bacterial infection of the bloodstream. Enteral feeding using gastrostomy, or jejunostomy tubes may be necessary. Short-term use of nasogastric feeding tubes can also provide important nutrients in animals that will not eat on their own.

PAIN CONTROL AND PATIENT COMFORT

While tachycardia can be a sign of poor oxygen delivery, it is also the result of pain and distress. Animals in constant stress are immunosuppressed. It is vital to the care of the patient that it be made as comfortable as hospitalization will allow. Often patient comfort takes a back seat to convenience in a busy hospital. The appropriate use of analgesics, sedatives, padding, bandage changes and personal contact will have positive effects on the patients overall sense of well-being. A stressed patient requires more oxygen than one resting comfortably.

CONCLUSIONS

The primary veterinary hospital is the most important element to the successful outcome of an emergency case. From the initial phone call, through admission, and throughout hospitalization, the first responders are in the best position to triage vital organ function and patient comfort. With a systematic, ABC, approach to changing patients conditions, life-threatening complications will be identified while there is time to make adjustments in treatment, reverse the process and give the animal time to heal.

FLUID THERAPY

Tim Hackett, DVM, MS, Diplomate ACVECC
College of Veterinary Medicine
Colorado State University, Fort Collins, CO

While the importance of fluid therapy cannot be overstated, the decisions of when, how, how much, and what type of fluid are not always clear. Water is essential to life. Water balance is a delicate interrelationship of forces keeping all fluid compartments saturated without overloading any part of the system. The purpose of this talk is to review the when, how, how much, and what types of fluids to use in a variety of common situations familiar to the small animal practitioner.

HISTORY AND PHYSICAL EXAMINATION

When evaluating fluid needs of a patient, it is useful to know the animal's exact body weight before the onset of illness from the owner or from current medical records. If there are acute decreases in body weight, most of these losses can be attributed to water losses. This will allow a more accurate assessment of dehydration.

A thorough physical examination should be performed; assuming fluid losses are not life threatening. If however, your quick assessment suggests life-threatening complications (abnormal mucous membrane color, abnormal capillary refill times, tachycardia, tachypnea, weak pulse, cool extremities, obvious blood loss, etc.), and then your first goal of fluid therapy will be to save the life of the animal. A thorough physical examination will have to be postponed and shock fluid therapy initiated to stabilize the patient's condition.

Although subjective, physical examination findings are important and should be used when assessing the degree of dehydration. As baseline body weights are not often available, the practitioner must be aware that the assessment of fluid losses is only an estimate; in fact, actual losses frequently are much greater.

Third-space losses involve the accumulation of large fluid volumes in cavities such as the pleural or peritoneal space and intestinal or gastric lumen, or in tissues around fracture or trauma sites. These losses result relative hypovolemia without predictable changes in body weight. Patients with extensive third-space losses are excellent candidates for colloid replacement. With their large molecular size and molecular weight. These compounds stay within the vascular space and help pull water back into circulation.

THE EMERGENCY PHASE

When a patient is hypotensive and has clinical signs of shock, intravascular volume is a priority. If there are no clinical signs of shock, one can proceed to rehydration and fluid maintenance.

The volume of fluid required is loosely based on the patient's weight, but you should be prepared to administer a full blood volume each hour if crystalloid solutions are being used. In the dog this will be about 90 mL/kg/hr. Cats are uniquely sensitive to fluid loading and should receive no more than a plasma volume in an hour (44 mL/kg).

By dividing the total shock fluid volume into 1/4 volumes (22 mL/kg) and close monitoring, one may determine when it is appropriate to move to the second phase of fluid resuscitation (rehydration phase). If the clinical signs of shock resolve after the first 10 minutes, there is no need to proceed with another bolus of fluid. It is now time to proceed to rehydration and maintenance.

One must be cautious about overhydration and hemodilution. Overhydration during the emergency phase is most likely to occur when large volumes are administered to animals with pulmonary contusions, pre-existing pulmonary edema, aspiration pneumonitis, hypoproteinemia, brain injuries, and congestive heart failure.

THE REPLACEMENT PHASE

The volume of fluid administered during the dehydration phase is based on an assessment of fluid needs for (1) returning the patient's status to normal (deficit volume), (2) replacing normal ongoing losses (maintenance volume), and (3) replacing continuing abnormal losses (continuing losses volume).

Maintenance volumes are **normal ongoing losses**. Ongoing losses are divided into **sensible** and **insensible** losses. Sensible losses can be measured and are water losses in the urine and feces. Insensible losses are normal but are not easily quantitated. These water losses occur during panting or sweating. One third of the maintenance volume is made up of the insensible volumes and two thirds, sensible volumes. Traditionally, maintenance volumes have been estimated to be:

60 mL/kg/day

Another formula assumes the basal amount of fluid required is equals basal caloric requirements.

(30 X kg BW) + 70

Because each patient is different, body weight will need to be assessed daily to adjust maintenance fluid volumes so the dehydrated patient gains weight and the hydrated patient maintains body weight. While making sure the patient is getting enough fluid, the clinician and nursing staff need to be aware of signs of fluid excess. Patients with heart or pulmonary problems may lose fluids into the lungs. These patients will become tachypneic, hypoxic, and develop pulmonary crackles.

THE MAINTENANCE PHASE

The last phase of fluid therapy is the maintenance phase. At this point, the patient has received enough fluid to compensate for shock (if necessary) and has had a partial replacement of any deficit volume. Chronologically, this phase begins no sooner than 24 hours after fluids were begun. Objective signals that the patient is ready to be placed in the maintenance phase are an absence of clinical signs of shock or dehydration, and the body weight will have increased by at least the percentage of dehydration already corrected. During the maintenance phase, clinicians will be providing both maintenance volumes and continuing losses volumes.

PARENTERAL FLUID SOLUTIONS

Dextrose Solutions

Because glucose is rapidly metabolized to carbon dioxide and water, the administration of dextrose is physiologically equivalent to administering distilled water. Thus, the main indication for the use of dextrose in water is to provide free water to replace insensible losses or to correct hypernatremia resulting from a water deficit. When added to crystalloid solutions, D5W is also useful in providing an intracellular carbohydrate source in patients with sepsis. Whenever dextrose is given, it is quickly metabolized to water, and the water will redistribute to the intracelleular fluid (ICF) and extracellular fluid (ECF) spaces in volumes commensurate with the water volumes in each compartment.

Dextrose in water should not be used as a maintenance fluid, as it will lead to dilution of all electrolytes. For a patient in shock, D5W is not generally recommended as a replacement fluid; it will be metabolized quickly, and the water generated will be distributed for the most part, to the ICF space and provide minimal expansion of the intravascular space. Administration of D5W subcutaneously may cause electrolyte movement into these tissues and may lead to a decrease in circulating blood volume and shock.

Crystalloid Solutions

"Crystalloids" refers to solutions that are isotonic with plasma and contain sodium as their major osmotically active particle. Crystalloid solutions such as Ringer's lactate or 0.9% sodium chloride (physiologic saline) distribute evenly in the extracellular space when administered intravascularly. Only 25% of the administered crystalloid solution will remain in the intravascular space of the ECF compartment after 1 hour. Equilibrium within the ECF compartments occurs within 20 to 30 minutes after infusion.

Physiologic saline (0.9% NaCl) is often called "normal saline." It contains normal levels of sodium ions (154 mEq/L) but abnormally high levels of chloride ions (154 mEq/L) and is considered an isotonic fluid (310 mOsm/L). "Isotonic" implies that the fluid has the osmolality of the extracellular compartments (290 to 310 mOsm/L). Normal saline is used for acute extracellular volume expansion. It is useful as a replacement fluid in the treatment of hyperkalemia and in the treatment of hyponatremia as seen in hypoadrenocorticism. It should not be used in animals with congestive heart failure, as sodium restriction is normally part of the therapy. It also recommended that physiologic saline not be used in animals with liver disease because of the potential for sodium-overloading resulting from these animal's inability to metabolize aldosterone.

Half-strength saline (0.45% NaCl) is an excellent maintenance fluid. A good choice whenever blood sodium levels begin to climb with long-term crystalloid fluid therapy. It is usually combined with dextrose (2.5%) and potassium chloride. The fluids used for maintenance fluids are meant to replace electrolytes normally lost each day. When insensible and sensible (urine) electrolytes are quantitated, an animal will normally lose 40 to 60 mEq/L of sodium and 15 to 20 mEq/L of potassium. Thus, if you continue to use replacement solutions such as Ringer's, 0.9% saline, Ringer's lactate, Normosol-R, or Ringer's acetate, hypernatremia and increased urinary potassium losses (leading to hypokalemia) may result.

In addition, 0.45% saline is the fluid of choice for animals predisposed to sodium retention; for example, those with congestive heart failure or liver disease. Hypernatremia is uncommon in the dog and cat. When the serum sodium does exceed 156 mEq/L, either D5W or 0.45% NaCl with 2.5% dextrose should be considered as a preferred fluid.

Hypertonic saline (3%, 5%, and 7%) is considered a possible drug for the treatment of shock. The rationale for use of these solutions is that they induce rapid expansion of the ECF fluid compartment, resulting in water movement from the ICF compartment to the ECF compartment. The drawback to this approach is the realization that there is also an expansion of the interstitial space because of the rapid redistribution of crystalloid solutions. Also, the intracellular dehydration that occurs with this approach may adversely affect cellular function. These fluids should only be given intravenously and should be administered slowly to avoid inducing pulmonary edema.

Ringer's solution is a crystalloid replacement fluid. It is more of a balanced replacement solution than LRS, 0.9% NaCl in that there is both calcium (4 mEq/L) and potassium (4 mEq/L) ions, along with sodium (147 mEq/L) and chloride (155 mEq/L). Because of the ionic concentrations, Ringer's solution is often used as a replacement solution in cases of metabolic alkalosis. When the alkalosis is the result of vomiting losses from the upper gastrointestinal tract, Ringer's solution supplemented with potassium chloride will be an excellent fluid.

In diabetes mellitus, Ringer's solution is a good fluid for replacement. Previously, concern was expressed about the sodium and potassium content in Ringer's solution. With the polyuria of diabetes, significant sodium, potassium, and water losses must be replaced. Following ionic replacement, one must consider the influence of sodium on the tonicity of the plasma. Because glucose also increases osmolality, there is the theoretic possibility of cerebral edema. Fortunately, this does not appear to be an important clinical entity in animals.

In diabetes mellitus, the initial plasma potassium levels usually are elevated. This is the result of a metabolic acidosis in diabetes mellitus. Remember, potassium is predominantly an intracellular ion, and when it is elevated on a biochemical profile it is usually are the result of an exchange whereby hydrogen ions move intracellularly and potassium ions move into the plasma. As fluids and insulin are administered, potassium ions move intracellularly, revealing the true hypokalemia seen with diabetes. Thus, potassium chloride usually is required. Before the patient's electrolyte status is determined, the potassium in Ringer's solution will be adequate and will not exacerbate the extracellular hyperkalemia. As insulin is administered, at least 20 mEq of potassium chloride per liter should be added.

Buffered crystalloid solutions include Ringer's lactate and solutions such as Normosol-R that contains both acetate and gluconate. With either of these balanced electrolyte solutions, the buffer will supply bicarbonate. Lactate is metabolized by the liver to form bicarbonate, and muscles and peripheral tissues metabolize acetate to bicarbonate.

Buffered crystalloid solutions are useful in the treatment of mild to moderately severe metabolic acidosis. Importantly, the lactate of lactated Ringer's solution does not contribute to the formation of lactic acid.

Colloid Solutions

Colloid solutions include albumin, fresh-frozen plasma, whole blood and synthetic colloids such as the dextrans (dextran-40 and dextran-70), hetastarch and purified cell-free hemoglobin (Oxyglobin®). They act primarily to expand the plasma volume. The rationale for using colloid solutions is from the maldistribution of extracellular water, with relative expansion of the interstitial space water, in the face of a plasma volume deficiency with traumatic and septic shock. This maldistribution of interstitial space water will predispose the patient to pulmonary edema and acute respiratory distress syndrome.

With colloid solutions such as the dextrans, the molecules are distributed in the ECF compartment, mainly the intravascular space. The particle sizes of the various dextrans affect the duration of their presence within the intravascular space and therefore the duration of volume expansion. Dextran-40 contains particles with molecular weights ranging from 10,000 to 80,000. Dextran-70, and hydroxyethyl starch (Hetastarch) contains particles with a molecular weights of 40,000 to 100,000. The half-life of particles with molecular weights of 14,000 to 18,000 is 15 minutes, whereas particles with molecular weights greater than 55,000 have half-lives of several days. As a general statement, only 20% of dextran-40 and 30% of dextran-70 remain in the circulation for more than 24 hours.

Indications for the dextrans include volume expansion and promotion of peripheral blood flow. Studies have shown dextrans to improve survival and hemodynamic parameters in shock. The resultant volume expansion following the use of dextrans is at the expense of the intracellular water.

Plasma is another colloid solutions and is often underused by veterinarians. It is easy to collect and, when frozen, is considered a stable colloid for 2 to 5 years. Fresh frozen plasma is frozen within 6 hours of collection at –70°C and is stable for 1 year (after one year it can still be used for its colloidal effect as describe for regular plasma. Plasma contains important proteins (albumin and globulins), which are useful in liver failure, hemodilution, and hypoproteinemia. An important use of fresh-frozen plasma is for specific or multiple clotting factor replacement. It is not used for the routine management of acute volume deficits when crystalloid solutions or commercial synthetic colloids work as well. The usual clinical dose of plasma is 5 to 10 mL/kg. Fresh-frozen plasma should be administered within 6 hours of thawing to obtain the maximum amount of clotting proteins. Compatibility should be evaluated when previous transfusions have been performed.

Human albumin is available in 5 and 25% solutions. It is felt that one unit of 25% albumin provides the same amount of albumin as contained in one unit of K9 plasma. When available it may be an economical alternative to massive plasma transfusion in critically hypoproteinemic patients. Because it is a human protein patients may become sensitized to the product. It is recommended that it be clear in the patients record if they receive human albumin and repeated dosing (weeks or months later) been approached with caution.

Whole blood is the colloid administered most commonly by veterinarians. It has the advantages of availability and ease of collection and storage. The most common uses of whole blood are for anemia and severe hemodilution. Although anemic patients may not need the plasma portion, whole blood will continue to be used routinely. As anemia is generally defined as a decrease in red blood cells, the use of packed red blood cells (where the plasma has been removed thereby concentrating the red blood cells) is the most logical means of stretching the usefulness of a unit of whole blood and also of providing needed blood components.

A unit of whole blood contains approximately 450 mL of red blood cells, plasma, white blood cells, and platelets. At the end of 24 hours of storage, very few platelets within the whole blood are hemostatically effective.

Oxyglobin is a purified bovine hemoglobin available to veterinarians. It is currently only approved for use in dogs but has been used in many species where whole blood was unavailable. Through purification, the nephrotoxic effects of free hemoglobin have been eliminated. Oxyglobin is a potent colloid with all the volume-expanding properties of a synthetic colloid and the added benefit of increased oxygen carrying capacity. Oxyglobin can be stored at room temperature for up to 3 years. It requires no cross matching (as there are no red blood cell surface antigens), and may improve hemodynamics by increasing vascular tone in some states of shock. The major disadvantage to Oxyglobin is its short duration of action (24 to 48 hours), the effect of free hemoglobin on some blood chemistry tests, and the increase in afterload that may be seen in euvolemic animals.

USE OF LACTATE MONITORING

Tim Hackett, DVM, MS, Diplomate ACVECC
College of Veterinary Medicine
Colorado State University, Fort Collins, CO

Hyperlactatemia and lactic acidosis are important features of shock. Lactate and lactic acid have been recognized as a cause of acidosis in metabolically active tissues (exercise) and poorly perfused tissues (circulatory shock). Lactate, a metabolite formed during the oxidation of glucose, accumulates in anaerobic tissues. Lactate production enables energy production to continue during anaerobic conditions. By converting excess pyruvate to lactate, the cell regenerates NAD$^+$ for ongoing glycolysis. Hyperlactatemia occurs whenever the rate of lactate production exceeds that of lactate extraction from the blood. When its production exceeds extraction, high circulating levels can accumulate. Patient-side tests of lactate can be useful in assessing a patient's whole body perfusion status. Normal blood lactate is 1.5 to 2.5 mmol/L. A blood lactate concentration in the range of 3 to 5 mmol/L constitutes a mild increase, 5 to 10 mmol/L is a moderate increase, and greater than 10 mmol/L represents a severe elevation. Hyperlactatemia is defined (in people) as a blood lactate concentration of 2 to 5 mmol/L without metabolic acidosis. Lactic acidosis (again a human definition) is a blood lactate concentration $\geq$ 5 mmol/L with an arterial pH below 7.35. Glycolysis often works faster than the oxidation of pyruvate. For this reason hyperlactatemia can occur in conditions which favor glycolysis (sepsis, alkalosis, or during glucose infusions) and during times of tissue hypoxia. Tissue hypoxia occurs when energy requirements outpace aerobic metabolism, as in exercise, circulatory shock, or seizures. Clinically hyperlactatemia is most often due to poor perfusion and inadequate tissue oxygen delivery. Lactate concentration in the blood is a quantitative measure of tissue hypoperfusion and a valuable measure of the severity of systemic oxygen delivery. This makes it useful when trying to assess the response to treatment in critically ill people and animals.

Lactate is either converted into pyruvate or eliminated from the body. The liver clears most of the lactate load with the kidneys also playing a role. The Cori cycle provides a path for these tissues to clear lactate while providing glucose to tissues favoring this energy substrate. The normal elimination half-life of lactate is less than 1 hour but can increase to over 2 hours with disease.

SAMPLE COLLECTION

Patient disposition, blood sampling technique, and sample handling can affect the measurement of plasma lactate. Prolonged venous occlusion and restraint can cause mild elevations in lactate concentration (2.5–3.5 mmol/L). Muscular activity during our around the blood sampling is an important variable, with levels as high as 6 to 7 mmol/L seen in normal dogs which exercise before venipuncture or in those with generalized muscle fasciculations (muscle tremors or seizures). Prolonged vascular stasis (holding off a vein) may artificially increase measured blood lactate. If there will be a delay in testing, blood samples should be held on ice, or separated from red blood cells. If the sample is analyzed within 30 minutes, the values should be fairly consistent. Lactate concentration in blood samples held at room temperature rise about 0.2 mmol/L after 30 minutes. This is thought to be due to glycolytic activity in red blood cells.

MEASURING BLOOD LACTATE

Originally, lactate measurement took a relatively large quantity of blood and the analysis could take over an hour. Today, blood lactate can be measured quickly using microliter samples of whole blood or plasma. Numerous patient-side systems are in use and all use similar enzymatic amperometry methodology to determine lactate concentration. The drive to create a quick, portable, lactate analyzer came not from the critical care/emergency fields, but from sports medicine. Endurance athletes and their trainers looking for objective ways to identify target heart rates knew that lactate levels often determine an athletes ability to go faster and farther. Lactic acid production by skeletal muscles must be balanced by the body's ability to clear the lactate. This lactate threshold becomes an important variable. By developing quick, small blood volume tests, athletes and trainers can precisely determine an athlete's lactate threshold and provide targeted training.

DIAGNOSTIC AND PROGNOSTIC VALUE OF LACTATE MEASUREMENT

As with all objective data, lactate measurement must be interpreted along with other patient care variables. Clinicians would like to just look at a number and gain insight into the patient's ability to deliver oxygen. Ideally it would be great if we could get an idea of prognosis based on that number. Admission lactates that are above normal only indicate that lactate production exceeds lactate clearance. Is the patient active? Did it just come from a walk/run? Did the patient struggle when the sample was obtained? These are important questions as clinicians look to other signs of impaired tissue oxygenation. Equally important, a normal blood lactate just tells the clinician that lactate clearance is keeping up with lactate production. A patient with seriously impaired oxygen delivery (shock) that hasn't exceeded its lactate clearance mechanisms could have a normal blood lactate.

There are some veterinary examples making good use of admission lactate values. A retrospective study of 102 dogs with gastric dilatation volvulus from the University of Pennsylvania showed that in the prediction of gastric necrosis, a plasma lactate greater than 6.0 mmol/L had a specificity of 88% and a positive predictive value of 75% but sensitivity was only 61%. Survival in these dogs was 99% if the plasma lacate was less than 6.0 mmol/L but only 58% if it was greater than 6.0 mmol/L. The same group also looked at plasma lacate in dogs with congestive heart failure from valvular disease and cardiomyopathy. In these cardiac patients, plasma lactate was significantly higher in nonsurvivors. In a prospective study of 16 dogs and cats with bacterial peritonitis and 55 with other causes of abdominal effusion, PLC in abdominal fluid from bacterial peritonitis was significantly higher than in nonbacterial effusions; however, the degree of overlap between groups limited its usefulness in individual animals.

More important than admission lactate is what happens to that lactate as we begin treating our patients. If our interventions result in improved oxygen delivery to tissues and improved renal and hepatic lactate clearance, our patient's lactate should return to normal. However, if our patient's blood lactate climbs in the face of treatment we are losing the battle and more aggressive measures need to be found to reverse the anaerobic conditions affecting our patients.

ABCs OF ACID–BASE

Justine A. Lee, DVM, Diplomate ACVECC
College of Veterinary Medicine
University of Minnesota, St. Paul, MN

Have a new graduate working for you who keeps bugging you to buy a blood gas machine? Not sure what extra information that blood gas might tell you anyway? Intimidated by all those scary, acid–base numbers? Can't remember how to interpret a blood gas to save your life (or your patient's?). With the improvement in emergency medicine and critical care, the use of blood gas analysis has become more prevalent. Devices such as I-STAT® or NOVA® are available as bedside testing, with results available within just minutes. This requires maintenance of the equipment, training for analysis of the data, and the technical skill to obtain the sample. Depending on the number and types of cases that are seen at your practice, along with the commitment of professional personnel to collect the samples and interpret the results, the use of blood gas analysis is extremely useful in the critical care or emergent setting. Not only can blood gas analysis be used to evaluate underlying disease mechanisms, but it may also aid in potential treatment interventions (ie, the decision to use bicarbonate therapy, to utilize positive pressure ventilation, or to treat with oxygen therapy).

BLOOD GAS ANALYSIS

Blood gas analysis is the determination of the pH, partial pressure of oxygen (PO$_2$), and partial pressure of carbon dioxide (PCO$_2$) of blood. Blood gases allow clinicians to evaluate the acidity of the blood, the overall acid–base status, the respiratory and metabolic contributions, and the pulmonary function. The HCO$_3^-$ is a measure of the *metabolic* component, while the PCO$_2$ is a measure of *ventilation* and is the respiratory component of a patient's acid-base status.

One of the first steps to blood gas analysis is looking at the pH. An "acidemia" is defined as a pH below normal ("acidemia" is acidosis of the blood, to be differentiated from an "acidosis" alone), while a pH above the range is an alkalemia. Severe acidemia ($<$ 7.1) is associated with altered enzymatic activity, decreased cardiac output, impaired renal and hepatic blood flow, decreased arterial blood pressure, neurological alterations, and detrimental cardiovascular consequences (ie, decreased cardiac contractility). Acidosis may also shift the oxygen-hemoglobin dissociation curve to the right, result in insulin resistance, and cause hyperkalemia (by transcellular shifting of K$^+$ for H$^+$); therefore, prompt recognition and treatment should occur. Neurologic signs may also be present with alkalemia, although this is less commonly clinically seen.

An acidosis or alkalosis can be characterized by being metabolic or respiratory in origin, and is due to an accumulation of acid or base, respectively. Metabolic acid-base derangements may be the result of numerous disease processes. **Metabolic acidosis** is the #1 disturbance commonly seen in veterinary medicine, and is characterized by decreased plasma HCO$_3^-$ concentrations and decreased pH. It is most commonly seen with these four causes: diabetic ketoacidosis (DKA), toxicities (eg, ethylene glycol, aspirin), renal failure, and lactic acidosis. **Metabolic alkalosis** is due to increased HCO$_3^-$ concentrations and an increased pH and is most commonly seen with pyloric outflow obstruction or loop diuretic administration. Rarer causes for metabolic alkalosis include hypochloremia, penicillin derivatives, and excessive alkalinization therapy with bicarbonate. As for respiratory conditions, alveolar hypoventilation leads to **respiratory acidosis** which is characterized by increased PCO$_2$ (which simplistically, is an "acid"). Alveolar hyperventilation leads to **respiratory alkalosis**, which is characterized by decreased PCO$_2$ levels ("blowing off" acid). These four primary acid–base disorders are **simple disorders**; in other words, the acid-base abnormality is limited to a primary disorder and its expected adaptive response. Mixed acid–base balance may occur when multiple processes are occurring and is most commonly seen with a "normal" pH. A **mixed disorder** is the presence of two or more separate primary acid–base abnormalities in the same patient, and should be suspected when the adaptive response exceeds or falls short of that expected.

1. The lower the pH, the more acidic a fluid is; the higher the pH, the more basic.
2. Increasing the PCO$_2$ lowers the pH and therefore has an acidifying effect on pH.
3. Decreasing the PCO$_2$ increases the pH and has an alkalinizing effect on pH.
4. Increasing the HCO$_3^-$- increases the pH and has an alkalinizing effect on pH.
5. Decreasing the HCO$_3^-$ decreases the pH and has an acidifying effect on pH.

Table 1. Normal Arterial Blood Gas Values

	Dog	Cat
pH	7.35–7.46	7.31–7.46
PCO$_2$ (mmHg)	32–43	26–36
HCO$_3^-$ (mEq/L)	18–26	14–22
BE	+1 to –5	–2 to –8
PaO$_2$	80–105	95–115

(From DiBartola's Fluid Therapy in Small Animal.) Practice, 2000).

Primary Abnormalities

- Metabolic acidosis (– BE, low HCO$_3$)
- Metabolic alkalosis (+ BE, high HCO$_3$)
- Respiratory acidosis (high pCO$_2$)
- Respiratory alkalosis (low pCO$_2$)
- Hypoxia

In general, the steps for interpretation of blood gas analysis should be the following:

1. pH = acidemic vs. alkalemic?
2. Base excess (BE) = truest component of metabolic component
3. pCO_2 = evaluation of respiratory component
4. Compensatory?
5. Hypoxic?
6. Alveolar-arterial (A-a) gradient
7. Do these changes correspond to the clinical picture?

First, determine if the pH is acidemic, alkalemic, or in the normal range. A normal pH with other disturbances (abnormal PCO_2, HCO_3^-, etc.) is suggestive of a *mixed acid-base* or potentially *compensated* disorder. Evaluate your base excess (BE), which is the amount of titratable acid necessary to bring a pH back to normal irrespective of the respiratory component; in other words, BE is your "truest" interpretation of your metabolic component. If this is excessively negative, you have a primary metabolic acidosis. Next, evaluate the metabolic (HCO_3^-) and respiratory (PCO_2) components. Calculate the degree of compensation to see if the body has compensated for its disease process. Finally, evaluate the blood gas result to see if it corresponds to the clinical picture of your patient.

Important diagnostic and treatment information can be ascertained from an arterial (ABG) or venous blood gas (VBG). The primary differences between an ABG and VBG are the ability to evaluate PO_2 (which is only accurate in an ABG), and a 5 to 10 mmHg difference in PCO_2 (with the venous side having a higher $PvCO_2$). For example, a dog with a pH of 7.0, PaO_2 of 60 mmHg, PCO_2 of 26 mmHg, HCO_3^- of 9 mEq/L, and a BE of –18 has an acidemia, a metabolic acidosis, and hypoxemia. Buffer therapy such as sodium bicarbonate and oxygen therapy should be considered while a search for the underlying metabolic condition is initiated. On the other hand, a cat with a pH of 7.23, pvO_2 of 33 mmHg, PCO_2 of 68 mmHg, HCO_3^- of 25 mEq/L, and a BE of +2 has an acidemia with a respiratory acidosis that has not yet compensated. This patient would benefit from positive pressure ventilation; however, because this is a venous sample, one cannot evaluate the severity of hypoxia. Buffer therapy in this case could be potentially harmful, as bicarbonate is converted to water and CO_2 (which must be "blown off") which may worsen the respiratory acidosis.

A pH in the normal range does not necessarily indicate the absence of acidosis or alkalosis, as an abnormal PCO_2 or HCO_3^- may be due to compensatory mechanisms or multiple simultaneous pathologies which "balance" each other. The clinician must therefore be vigilant in reading the entire blood gas. Lastly, many blood gas analyzers have the capability to measure electrolytes and lactate. These values are also imperative in evaluating and understanding the acid-base abnormality or severity of hypoperfusion (lactate).

COMPENSATION

The body will attempt to compensate for the severity of the primary abnormality, but will **never** overcompensate. Remember that a change in the respiratory or metabolic component produces an **opposite** response to the other component to bring pH back to normal. Respiratory compensation via the lungs is extremely rapid and occurs within minutes, while the kidneys compensate more slowly over the course of hours to days. For example, if an animal has a severe metabolic acidosis (ie, acute on chronic renal failure), it should ideally compensate by hyperventilating and "blowing" off this excess acid (pCO_2). One must consider whether enough time has passed for the animal to compensate and that the underlying disease has been stable during this time for compensation.

Metabolic acidosis:	↓ $PaCO_2$ of 0.7 mmHg per 1 mEq/L ↓ HCO_3
Metabolic alkalosis:	↑ $PaCO_2$ of 0.7 mmHg per 1 mEq/L ↑ HCO_3
Respiratory acidosis:	↑ 0.15 to 0.35 mEq/L HCO_3 per 1 mmHg ↑ $PaCO_2$
Respiratory alkalosis:	↓ 0.25 to 0.55 mEq/L HCO_3 per 1 mmHg ↓ $PaCO_2$

Causes for METABOLIC ACIDOSIS

- GI loss of bicarb
  - Diarrhea
  - Vomiting
- Renal loss of bicarb
- Renal hydrogen retention
- IV nutrition
- Dilutional acidosis

Causes for METABOLIC ALKALOSIS

- Lasix administration
- Pyloric outflow obstruction
- Hypochloremia
- Hypokalemia
- Hypermineralocorticism
- Penicillin derivatives
- Contraction alkalosis
- Excessive alkalinization therapy

VENOUS BLOOD GAS ANALYSIS (VBG)

In severely dyspnea patients or in feline patients, the stress of restraint for ABG sampling is contraindicated. Rather, the use of venous blood gas analysis with pulse oximetry interpretation can be used together and is often times as beneficial as ABG results. For the evaluation of acid-base parameters, a venous blood gas is an attractive alternative as it does not require arterial sampling. Venous samples can be interpreted as

Causes for RESPIRATORY ALKALOSIS

- Hypotension
- Fever
- Sepsis
- Excitement
- Pain
- Brain tumor
- PTE
- Early pulmonary parenchymal disease
- Cytokine release in SIRS
- Inappropriate ventilator settings
- Compensation

Causes for RESPIRATORY ACIDOSIS

- Hypoventilation
    - Neuromuscular
    - Medullary dysfunction
        - General anesthesia
        - Intracranial disease
    - Cervical disease
- Airway obstruction
    - Large airway obstruction
        - Laryngeal paralysis
        - Tracheal collapse
    - Small airway obstruction
        - Chronic airway disease
        - Bronchoconstriction
- Thoracic wall problems
    - Open pneumothorax
    - Flail chest
    - Diaphragm compression
    - Pleural space filling disorder
    - Pleural fibrosis
- Pulmonary parenchymal disease (late)
- Inappropriate ventilator settings
- Dead space re-breathing
- Bicarbonate therapy
- Compensation for metabolic acidosis
- Malignant hyperthermia
- Brain tumor

Causes for HYPOXIA

- Decreased FIO_2
- Inadequate O_2 supply
- Hypoventilation
- Ventilation/Perfusion mismatch
- Anatomic shunting
- Diffusion impairment
- Low oxygen delivery
- Low cardiac output

previously described for an arterial sample, with three known exceptions:

- The PCO_2 is approximately 5–10 mmHg higher in the venous vs. the arterial system.
- One cannot assess PO_2 on a venous sample. Only an arterial PO_2 can provide information regarding the oxygenation function of the lungs. However, with pulse oximetry, SpO_2 (oxygen saturation) can be correlated with an oxygen-hemoglobin dissociation curve and the pO_2 can then be deducted. Pulse oximeter + VBG = ABG.
- When peripheral vasoconstriction, severe shock, hypovolemia, or low flow states (ie, saddle thrombus, tourniquet application) occur, a peripheral venous sample may not be accurate. These conditions may result in tissue acidosis which may increase CO_2; technically, ventilation *should* keep pace with delivery of CO_2 from the tissues to the lung. Remember that a mixed or jugular venous sample may better reflect the acid–base status of the patient than one from an artery of an affected limb (as long as the patient is not coagulopathic or thrombocytopenic).

OXYGENATION

The PO_2 is the partial pressure of dissolved oxygen and is directly measured by the blood gas analyzer. In order for oxygen to reach the arterial blood, there must be an adequate source of oxygen delivered (ventilated) to the lungs. In addition, adequate blood flow must pass by functioning alveoli with no impediment to diffusion into the blood. As over 95% of the oxygen in arterial blood is normally carried on hemoglobin, the amount of hemoglobin and its saturation are the main determinants of oxygen content (CaO_2). The oxygen content of blood is the amount of oxygen the blood can deliver to the tissues; any significant decrease can compromise the patient. The dissolved oxygen is in equilibrium with oxyhemoglobin and together makes up the oxygen content of the blood.

The PaO_2 coupled with the $PaCO_2$ provides the clinician with a tool to evaluate lung function. A low PaO_2 is referred to as hypoxemia and signals that there is inadequate oxygen supply (ie, empty O_2 tank on the anesthesia machine), hypoventilation (ie, neuromuscular disease or increased anesthetic depth), venous admixture (ie, ventilation/perfusion mismatch as in pulmonary parenchymal disease such as pneumonia), or a diffusion impairment (ie, neoplastic alveolar infiltration). A patient that is hypoxemic may benefit from oxygen supplementation and/or positive pressure ventilation; subsequent arterial blood gases or pulse oximetry can be used to monitor progression and response to therapy

The measurement of the severity of hypoxemia can be based on several calculations. One commonly used in the ICU setting is the **alveolar-arterial (A-a) gradient**. The use of this formula should be limited to assessment on room air (ie, FiO_2 of 21% or 0.21). The barometric pressure is represented by 760 mmHg, while the water vapor pressure is approximately 47. The respiratory quotient is represented as a denominator of 0.8 (or sometimes as a numerator as 1.2). Based on room air at sea level, this can be simplified to: $PAO_2 = 150 - PaCO_2/0.8$, where normal is 0–15 mmHg. Higher values are suggestive of underlying parenchymal lung disease (from ventilation:perfusion or V:Q mismatch or shunting), and chest radiographs should be done to evaluate for lung disease! Normal A-a values may be seen with hypoventilation (despite abnormal blood gas parameters).

$$PAO_2 = FiO_2\,(760\text{-}47) - PaCO_2/0.8$$

Another popular method for quantifying the lung efficiency is the **PaO_2:FiO_2** ratio. It allows for the comparison of samples obtained *despite different levels of oxygen supplementation*. Normal ratio levels should be 500 (ie, 100:0.21), while <300 is consistent with acute lung injury and < 200 is consistent with acute respiratory distress syndrome. For example, a patient with a PaO_2 of 80 mm Hg on room air has a PaO_2:FiO_2 ratio of 80/0.21 = 381. If this same patient is evaluated later on a FiO_2 of 60% with a measured PaO_2 of 170 mmHg, the PaO_2:FiO_2 ratio is 170/0.60 = 283 and therefore indicates less pulmonary function and a worsening of hypoxemia.

SAMPLING ERRORS

One consideration with arterial blood gases is that sampling errors may occur. For this reason, blood should be collected easily (without delay or excessive negative pressure) and anaerobically (avoiding the presence of air bubbles). It is important to obtain a free-flowing arterial or venous sample, as venous stasis or muscular activity can affect lactate or PCO_2. Samples should also be analyzed immediately; if not, they should be stored in ice water. Otherwise, venous contamination/collection, heparin dilution, delays in analysis, and non-anaerobic collections may affect the PCO_2 or PO_2. In addition, the following situations may also result in "false" results:

- Excess heparin within the syringe: low pH, pCO_2, HCO_3
- Exposure to room air or a large air bubble, which normally has a low $[PCO_2] \rightarrow$ diffusion down the gradient occurs, so the pCO_2 blood sample decreases and pH increases (less acid)
- Exposure to room air or a large air bubble, which normally has a high $[PO_2] \rightarrow$ diffusion down the gradient occurs, so that the pO_2 blood sample increases.
- Standing sample: increased PCO_2, decreased pH (higher temp, more change). Prevent this by putting the sample in an ice bath to prevent ↓ glucose and ↑ lactate due to glycolysis by cells.

CONCLUSION

Blood gas analysis provides valuable information to the emergency critical care clinician, and allows one to evaluate acid–base status, electrolyte function, perfusion (if lactate is available), ventilation, and oxygenation. This may serve to better understand the disease mechanisms, determine therapeutic intervention, and monitor improvement. Arterial or venous blood gas analysis can provide valuable insight into a patient's acid–base and ventilatory status. The use of blood gas analysis should be warranted in emergency and critical care cases, and interpreted with care to aid in improved quality care of these critically ill patients.

MISCONCEPTIONS ABOUT EMERGENCY AND CRITICAL CARE

Justine A. Lee, DVM, Diplomate ACVECC
College of Veterinary Medicine
University of Minnesota, St. Paul, MN

With the improvement in emergency and critical care, new modalities or approaches have recently arisen. These updated techniques are based on both veterinary and human scientific research and clinical experience and may refute older modalities. As a result, there are many misconceptions that should be updated and reviewed in our current application to veterinary medicine. With appropriate implementation in the clinical setting, we can help increase survival of our critically ill patients.

Some common misconceptions about emergency and critical care include:

- Do we give steroids in head trauma?
- Should I use steroids in shock?
- What are anti-inflammatory vs. immunosuppressive doses of steroids?
- Dextrose in intravenous (IV) fluids is always warranted in hospitalized animals to help maintain nutrition.
- Septic, shocky cats look just like septic, shocky dogs.
- VPCs should always be treated with lidocaine or procainamide.
- Analgesics should be withheld in critically ill patients because it causes respiratory depression.
- IV fluids: does it matter what bag I grab?

DO WE GIVE STEROIDS IN HEAD TRAUMA?

Recently, the use of steroids in head trauma in both human and veterinary medicine has been widely debated. While there is voluminous research in this topic, there are no experimental or clinical studies demonstrating a *clear* benefit of steroids in head trauma. In one human study, a meta-analysis of randomized controlled trials did not show a beneficial response from steroid therapy. Unfortunately, steroids have been associated with the following deleterious side effects:

- GI bleeding
- Hyperglycemia
- Immunosuppression
- Delayed wound healing
- Perpetuation of a catabolic state

The brain trauma foundation guidelines state that glucocorticoids are "not recommended for improving outcome or reducing intracranial pressure in head-injured patients." The "CRASH" study demonstrated that the overall mortality was statistically higher in those patients who were treated with steroids. In fact, recent studies have shown that human patients with head trauma and hyperglycemia have a *poorer* return to cognitive function than do euglycemic patients.

Why is hyperglycemia dangerous with head trauma or in any patient with brain ischemia (ie, epileptic, brain tumor)? Unfortunately, elevated glucose concentrations provide a substrate for anaerobic metabolism and glycolysis in the brain, worsening brain perfusion via the accumulation of the byproduct, lactic acid. In addition, hyperglycemic is associated with pro-convulsant effects, which is due to increased neuronal excitability. In a veterinary study by Syring et al, 52 dogs and 70 cats with head trauma were compared with 122 age- and species-matched control dogs and cats. In this study, the severity of head trauma was classified as mild, moderate, or severe, and blood glucose concentrations were recorded within 1 hour after admission. This study found that the blood glucose concentration was significantly associated with *severity* of head trauma in dogs and cats and was significantly higher in dogs and cats with head trauma than in the control animals. However, blood glucose concentration was not associated with *outcome*, which is divergent from human studies. This study may differ from human medicine in that overall cognitive function varies between veterinary and human patients (ie, our patients don't read!). These studies reiterate the importance that iatrogenic hyperglycemia should be *avoided* in patients with head trauma or cerebral ischemia (ie, seizuring dog, brain tumor patient) and that severe hyperglycemia in head trauma should potentially be treated with regular insulin therapy if warranted. When in doubt, it is best to withhold steroid therapy in head trauma patients to prevent hyperglycemia and other detrimental effects. Rather, osmotic agents such as mannitol have been found to be more beneficial to help decrease intracranial pressure.

Therapeutics to consider in head trauma patients *instead* of steroids include:

- Aggressive fluid resuscitation to help normalize or maintain blood pressure and maximize perfusion
- Oxygen therapy
- 15-30° head elevation
- Minimal jugular restraint or pressure
- Tight glycemic control

If IV fluid resuscitation alone does not help dilute and lower the glucose in hyperglycemic patients with head trauma, low dose 0.2 U/kg of regular insulin should be given IM every 2 to 4 hours for the first few hours to help lower blood glucose. This should be monitored frequently to ensure that the patient's blood sugar improves or that the patient does not become hypoglycemic, which would make neurologic monitoring even more difficult to evaluate.

Clinical Application

- Consider using mannitol at 0.5–2 g/kg IV over 20 to 30 minutes as needed for head trauma rather than steroids. This is particularly important if the patient develops "Cushings" reflex (ie, bradycardia with

concurrent hypertension), which is suggestive of severe cerebral edema and imminent herniation.
- Don't use steroids with head trauma until we have further evidence. Rather, use supportive care to increase perfusion to brain tissue (ie, IV fluids, oxygen) while decreasing intracranial pressure (ie, mannitol, head elevation)

NEW ANTI-INFLAMMATORY VERSUS IMMUNOSUPPRESSIVE DOSES OF STEROIDS

Traditionally, "shock doses" of steroids have been listed in emergency books at 4 to 6 mg/kg. Criticalists have moved away from giving steroids with trauma, due to potentially deleterious effects listed above. More recently, we have moved to different *doses* of dexamethasone sodium phosphate (DexSP). Anti-inflammatory doses of DexSP are generally considered 0.1 mg/kg, while immunosuppressive doses are as little as 0.25 mg/kg IV every 12 hours. For that reason, the 4 to 6 mg/kg dose in shock is no longer indicated. Remember that DexSP is approximately 8 to 15 times stronger than prednisone, so it is unlikely you need 40 mg/kg of prednisone with trauma!

Clinical Application

- Consider using low-dose DexSP for immunosuppression at the dose 0.25 mg/kg IV every 12 hours.
- Avoid the "shock doses" of steroids – if you are giving more than a few cc's, it's too much!
- While this newer dose of DexSP dose is lower, concurrent use of NSAIDS should still be avoided to minimize gastrointestinal effects.

DEXTROSE IN IV FLUIDS IS ALWAYS WARRANTED IN HOSPITALIZED ANIMALS TO HELP MAINTAIN NUTRITION

Dextrose supplementation in IV fluids is always warranted in ***hypoglycemic*** patients. However, in patients who are ***euglycemic***, the use of dextrose supplementation is not warranted, even for nutritional support. Why is extra dextrose bad? Recently, studies have shown that the effects of hyperglycemia are deleterious – in other words, increased insulin resistance may have secondary immunosuppressive effects. In addition, critically ill patients may already be hyperglycemic due to circulating excessive stress hormones such as glucocorticoids, catecholamines, and cytokines. Tighter glycemic control may help prevent cellular hypoxia by reducing endothelial damage and preventing cytopathic hypoxia. Human medicine (Van Den Berghe et al, NEJM 2001;345:1359-1367) recently found that intensive insulin therapy should be implemented in critically ill surgical ICU patients to prevent or treat hyperglycemia in *non*-diabetic patients, as *tight glycemic control* improved survival significantly. When intensive CRI regular insulin was used to maintain blood glucose between 80 and110 mg/dL, intensive insulin therapy reduced mortality during intensive care from 8.0% with conventional treatment to 4.6% ($P<0.04$). This was most significant in patients who stayed in ICU for > 5 days, and greatly reduced mortality from multiple-organ failure (MOF) with a proven septic focus. Overall, intensive insulin therapy "reduced overall in-hospital mortality by 34%, bloodstream infections by 46%, acute renal failure requiring dialysis or hemofiltration by 41%, the median number of red-cell transfusions by 50%... and patients receiving intensive therapy were less likely to require prolonged mechanical ventilation and intensive care."

How can we clinically apply this to veterinary medicine? The following steps should be considered when evaluating a critically ill hyperglycemic patient. First, diabetes mellitus (DM) must be ruled out. The diagnosis of DM should be supported based on the following: a urinalysis with evidence of glucosuria, clinical signs of pu/pd and weight loss, and persistent hyperglycemia and glucosuria on recheck. Second, considerations for hyperglycemia (non-diabetic in origin, such as stress hyperglycemia or severe hypoperfusion/hypovolemia) must be ruled out and treated appropriately. Like humans, dogs do not usually develop a stress hyperglycemia like cats. Rarely, dogs may develop the "stress of death" (SOD) hyperglycemia from *severe* shock and hypovolemia; if this is noted in dogs (ie, glucose > 160 mg/dL), patients should be thoroughly evaluated and volume resuscitated appropriately (once cardiogenic shock has been ruled out). Knowing that dogs only show a SOD hyperglycemia when they are potentially peri-arrest, it is imperative to consider aggressive resuscitation, if indicated. This SOD hyperglycemia should be treated with medical management first; if the hyperglycemia does not improve after several hours, the use of tight glycemic control with regular insulin therapy may be warranted. Finally, once treatment modalities have been initiated (such as IV fluid resuscitation, oxygen therapy, etc.), the use of regular insulin therapy can be considered with persistent hyperglycemia. It is important to reiterate that the theory of *tight glycemic control* may be more applicable in *dogs* pending more veterinary clinical research, as cats traditionally have a more profound stress hyperglycemia.

Finally, dextrose supplementation for nutritional support is not warranted, as it is not highly effective. If 5% dextrose is supplemented in 1 liter of fluids, it only provides 170 kcals/liter. For example, a typical 5 kg cat on IV fluids at 20 mL/hour will only receive 480 mL of fluids over the course of 24 hours, which amounts to only 80 kcal of nutritional supplementation within a 24-hour period. This cat's average nutritional requirement is approximately 220 kcals/day, and dextrose supplementation alone would fall significantly short of this. Increasing the fluid rate would potentially fluid overload the cat in an attempt to provide nutritional support (requiring 3 times maintenance!). Nor does this mean to add more dextrose into 1 liter of fluids, as this would significantly change the osmolality of the crystalloid and potentially become too hypertonic to deliver through a short-term peripheral catheter. We know that dextrose supplementation in IV fluids does not supplement enough RER, and we know that hyperglycemia in human medicine is associated with a higher mortality. Therefore, we should avoid over-supplementing dextrose to our patients who are able to maintain their own blood glucose.

Clinical Application

- In documented *hypoglycemia*, use IV boluses of dextrose (ie, 0.5 to 1.5 mL/kg of 50% dextrose, diluted 1:3 with saline) followed by a CRI of dextrose therapy until the animal is *euglycemic*.
- In patients that are already euglycemic, do not use routine dextrose supplementation to provide RER.
- Avoid supplementation > 5% dextrose through a peripheral catheter due to hyperosmolality, which would result in irritation to the vessel.
- In non-diabetic canine patients who are hyperglycemic (potentially from catecholamine release, stress, etc.), monitor the blood glucose. If it is persistently high (> 160 mg/dL), consider low dose regular insulin (IM) once the patient has been volume resuscitated or treated appropriately.

SEPTIC, SHOCKY CATS LOOK JUST LIKE SEPTIC, SHOCKY DOGS

Cats will be cats, and of course, have to do things differently! Cats have a unique physiologic response to shock, and it is often very different from their canine companion. The classic hyperdynamic shock state is rarely seen in cats (ie, brick, red, injected mm, tachycardia, bounding, pulses, etc.). Brady et al evaluated cats confirmed to have severe sepsis (based on necropsy findings) and evaluated pertinent history, physical examination findings, and results of hematologic and biochemical testing (n= 29 cats). Clinically, these septic cats were diagnosed with the following diseases: pyothorax, septic peritonitis, bacteremia secondary to gastrointestinal tract disease, pneumonia, endocarditis, pyelonephritis, osteomyelitis, pyometra, and bite wounds. In this study, clinical signs of severe sepsis in cats included physical examination findings such as lethargy, pale mucous membranes, poor pulse quality, tachypnea, hypo- or hyperthermia, signs of diffuse pain on abdominal palpation, bradycardia, and icterus. In addition, clinicopathologic abnormalities found in severe sepsis in cats included: anemia, thrombocytopenia, band neutrophilia, hypoalbuminemia, low serum alkaline phosphatase activity, and hyperbilirubinemia. This study showed how severe sepsis in cats is clinically different from canine patients with sepsis. Cats were characterized by lethargy, pale mucous membranes, signs of diffuse abdominal pain, tachypnea, bradycardia, weak pulses, anemia, hypoalbuminemia, hypothermia, and icterus. In other words, *septic cats are cold, flat, and bradycardiac*! The cause for the bradycardia is unknown, but factors such as parasympathetic stimulation, cytokine-induced myocardial depression (from myocardial depressant factor), and resistance to catecholamines (especially when hypothermic) are all proposed. Nevertheless, a sick, bradycardiac cat should make you *more* worried than a tachycardiac cat!

Clinical Application

- Bradycardiac cats should worry you more than tachycardiac cats!
- Search for causes of sepsis in bradycardiac, lethargic, pale cold cats.
- Consider doing tests such as CBC/CHEM/full body radiographs/UA/urine culture, routine abdominocentesis (or abdominal ultrasound) in this cat population to rapidly identify a cause for sepsis.
- Remember that cats show sepsis very differently from dogs.

VPCS SHOULD ALWAYS BE TREATED WITH LIDOCAINE OR PROCAINAMIDE

As with all drugs and pharmokinetics, there are pros and cons of using certain drugs. Anti-arrhythmic drug therapy is certainly beneficial in certain circumstances, as they may decrease the heart rate allowing for more time for ventricular filling (ie, beta blockers), and have mild anti-inflammatory properties (ie, lidocaine). However, with these same drugs come detrimental effects such as negative ionotropic effects, decrease myocardial function, increased requirement for defibrillation, and increased myocardial oxygen demand. Anti-arrhythmics can also be arrhythmiogenic in origin. In general, anti-arrhythmic therapy is warranted when patients have evidence of the following signs of poor perfusion: cold peripheral limbs, poor CRT, a prolonged CRT > 2.5 seconds, or tachycardiac > 170 (dogs) or >240 (cats). Similarly, if the ECG shows changes of malignancy such as "R on T" phenomenon, one should promptly consider anti-arrhythmics due to the increased risk of ventricular fibrillation. Finally, if the heart rate (HR) is > 170 to 180, one must investigate causes for tachycardia. The following step-wise problem tree should be considered with tachycardia:

- Immediately check a blood pressure (BP).
- If the BP is low (MAP < 60), consider a bolus of crystalloids (ie, LRS, Norm-R, saline) at 20 mL/kg IV over 15 to 20 minutes to see if this improves both the HR and the BP.
    - If it does improve, this tachycardia was likely due to hypovolemia.
    - A secondary bolus of crystalloid (or even a 5 mL/kg bolus of Hetastarch) can also be considered if mild to moderate improvement is shown, but the HR is still not within the normal range.
- If HR is > 170 to 180 (canine) and the BP is normal to slightly hypertensive, rule out pain.
- Consider analgesics
    - Hydromorphone at 0.1 mg/kg IV once, repeating every 4 to 6 hours as needed.
- If neither a fluid bolus or pain medication improve the HR, rule out the following causes for tachycardia and arrhythmias:
    - Electrolyte abnormalities
        - Blood gas
        - Treatment: potassium or magnesium supplementation, as indicated

- Hypoxia
  - Arterial blood gas or
  - Pulse oximeter
  - Treatment:
    - Oxygen supplementation
    - Treatment of underlying parenchymal lung disease
    - Reversal of sedation if hypoventilating (high PCO_2)
- Acidosis
  - Venous or arterial blood gas
  - Treatment: increase perfusion with IV fluids, if indicated
- Anemia
  - Packed cell volume
  - Treatment: IV fluid therapy (ie, crystalloids, colloids, blood products)

If, despite all these pro-active measures, the patient is still demonstrating tachycardia and arrhythmias, and if perfusion is compromised or the arrhythmia looks malignant on ECG, consider anti-arrhythmics:

- Lidocaine (1–4 mg/kg, IV, slow, followed by a CRI 25–50 µg/kg/min) should be promptly initiated (if ventricular in origin). Lidocaine is unlikely to have a beneficial effect in supraventricular arrhythmias, and its use should be reserved for arrhythmias ventricular in origin.
- Procainamide: if lidocaine appears to be ineffective (6–8 mg/kg IV slow over 5 minutes, followed by a CRI 25–40 µg/kg/min)

Clinical Application

- Evaluate patients for perfusion. If signs of poor perfusion are evident, these patients should be clinically treated for their poor perfusion, and treated with anti-arrhythmics if indicated.
- If patients show signs of good perfusion (ie, pink mm, strong synchronous pulses, CRT < 2 seconds, no pulse deficits), anti-arrhythmic therapy is not warranted.
- Treat the patient, not the arrhythmia or ECG!

ANALGESICS SHOULD BE WITHHELD IN CRITICALLY ILL PATIENTS BECAUSE IT CAUSES RESPIRATORY DEPRESSION

In the emergency room and ICU, we see patients who may have undergone thoracic trauma from bite wounds, contusions, pneumothorax, diaphragmatic hernias, rib fractures, etc. Other patients may have underlying pneumonia, congestive heart failure, or lung disease, or may be hypoventilating from pain or anesthesia. Often times, these patients have concurrent fractures which may be painful, and analgesia therapy should *not* be withheld in these patients. Many veterinarians are hesitant to use opioids in these critically ill patients due to the fear of hypoventilation or respiratory arrest. While it is imperative that these patients be monitored carefully, one should not hesitate to provide analgesia to these patients. Patients should be adequately volume resuscitated (once cardiogenic shock has been ruled out) first to maintain normal perfusion, treated with oxygen therapy if hypoxic, and then administrated analgesics once the patient has been assessed for neurologic function (with trauma cases).

A study by Berg and Orton evaluated arterial blood gases in patients underlying intercostal thoracotomy; these patients were treated with morphine and oxymorphone, and while hypoventilation was documented based on rising pCO_2, this was not clinically significant. Based on the paucity of literature showing respiratory depression from opioids, analgesic therapy should not be withheld from patients with lung disease. When in doubt, it is best to slowly titrated drugs to effect.

Clinical Application

- Patients should be treated aggressively to maintain oxygenation and perfusion with oxygen supplementation and carefully titrated pain control.
- Consider the following opioids and doses:
  - Hydromorphone: 0.1 mg/kg IV q 6 hours
  - Morphine: 0.5 mg/kg IM or SC q 3 to 4 hours
  - Fentanyl: 1–5 µg/kg/hour, followed by CRI
  - Torbugesic: 0.1–0.2 mg/kg IV q 1 or 0.2 hours to 0.4 mg/kg SC or IM every 1 to 2 hours
- Continue to carefully monitor tachypneic or dyspneic patients with pulse oximetry, respiratory rate and effort monitoring, arterial blood gas analysis, etc.
- When concerned about analgesic therapy in critically ill patients, consider *reversible* drugs in the event of an emergency. Reverse with: Naloxone 11–22 µg/kg IV or IM as needed (0.5–1 mL per dog!)
- Consider lidocaine patches over rib fractures, sternotomy sites, or flail chest sites. These can be safely used in both dogs and cats concurrently with opioids or NSAID therapy.

IV FLUIDS: DOES IT MATTER WHAT BAG I GRAB?

Recently, there has been discussion about what the safest IV fluid bag to grab is. Does it matter if you stock LRS vs. 0.9% saline vs. Norm-R vs. Plasmalyte on your shelves? In the event of an emergency, does it really matter? Recently, the misconception that LRS is always the safest choice for fluid therapy has been debated. When it comes down to it, most crystalloids are safe in replacing what you need with either dehydration or shock: free water and salt. Most of these balanced replacement or maintenance crystalloids provide a sodium level similar to the body, and for that reason, it is generally safe to go with the decision to pick an IV fluid choice closest to your patient's sodium.

LRS, a crystalloid replacement fluid, has a pH of 6.5, a Na^+ of 130 mEq/L, 4 mEq/L of K^+, and a Cl^- of 109 mEq/L. In addition, it has minimal Ca^{++} at 3 mEq/L. It also provides 28 mEq/L of lactate which is metabolized by the liver into bicarbonate to act as a safe buffer. It is important, however, to note that not all lactates are created equal! Lactate is available in two mirror images:

L-lactate ("L" for "living", as this is the enatiomer or version that our cells produce and utilize) and D-lactate ("D" for dead, the bad lactate). Both forms of lactate are present (50/50 mix) in LRS. It is been reported that the D-lactate can potentially promote inflammation by activating neutrophils and increasing the stickiness of endothelial cells. Lo and behold, saline, Hetastarch, and Dextran 40 can also increase neutrophil activation to a greater degree than LRS. While "pure" L-lactated Ringer's (with no bad D-isomer) is available from Baxter, remember that with day to day use, LRS is usually a safe fluid of choice. Not only is it balanced, but it provides small amounts of calcium and potassium. In clinical cases of hypocalcemia or hypokalemia however, additional supplementation is usually necessary. Secondly, LRS is considered an alkalinizing fluid due to the bicarbonate precursor lactate, and this is beneficial in patients who may have an underlying metabolic acidosis (i.e., from renal failure, ethylene glycol toxicity, lactic acidosis, or diabetic ketoacidotic state). The three main contraindications for using LRS are: liver failure, lymphosarcoma (LSA), and blood transfusions. Since lactate is metabolized by the liver to bicarbonate, metabolism may be compromised in patients with cirrhosis, icterus, portosystemic shunts, or underlying affected liver metabolism. Therefore, LRS should not be used in any patients with underlying liver disease. Secondly, patients with lymphosarcoma have been noted to be hyperlactatemic and have a decreased ability to metabolize lactate compared to normal dogs. This may be due to an increased preference for tumor cells to utilize glucose for energy via anaerobic metabolism, which results in the production of lactate. Lastly, patients requiring blood transfusions should not have the transfusion administered with LRS, as the small amount of calcium in LRS may bind with the citrate, resulting in micro- or macro- agglutination by activation of the clotting cascade.

Clinical Application

- When in doubt, any balanced replacement or maintenance crystalloid (ie, LRS, 0.9% NaCl, Norm-R, or Plasmalyte-148) is effective for volume replacement.
- In cases of liver failure, blood transfusion, or lymphosarcoma, LRS is contraindicated.
- If a blood transfusion is to be given, it should only be given with 0.9% NaCl.
- Chose a fluid choice with a sodium closest to your patient's sodium.

CONCLUSIONS

With the implementation of both clinical research and scientific research, improvement in treatment modalities have improved the overall quality of care and outcome in critically ill veterinary patients. Advances should be frequently updated in order to avoid perpetuating outdated modalities. Veterinarians can easily improve outcome with updated techniques which require simple diagnostics such as glucometers, opioid pain control, physical examination monitoring, and supportive care.

CURRENT CONCEPTS IN CPR

Steven L. Marks, BVSc, MS, MRCVS, Diplomate ACVIM
College of Veterinary Medicine
North Carolina State University, Raleigh, NC

Cardiopulmonary resuscitation (CPR), or the more comprehensive term *cardiopulmonary cerebral resuscitation* (CPCR), is still one of the most important interventions performed in human or veterinary medicine. This is especially true in veterinary medicine when dealing with emergency and critical critically ill patients. Although not performed frequently, it must be utilized in the appropriate situation and using the most effective techniques in order to maximize the possibility of success. Currently estimates of successful CPR in veterinary patients are reported to be less than 10% but this may vary from institution to institution. This figure compares favorably with survival rates reported for out of hospital cardiopulmonary arrest in human patients but is lower than reported survival rates for in-hospital arrests.

ADVANCE DIRECTIVES

Advance directives are a formal component of human medicine and have gained more importance in veterinary medicine. In generic terms, advance directives refer to information provided to a physician by a patient detailing what care should be provided if the patient is unable to make decisions. In veterinary patients, this equates to the primary care clinician having a detailed discussion with the pet owner concerning medical management of a pet who has had a life-threatening medical event. In more general terms and for the purpose of this discussion, this addresses whether the patient should be resuscitated if cardiopulmonary arrest occurs. This discussion should be documented in the medical record. There should be a way of identifying which patients have "do not attempt resuscitation" (DNAR) orders and the nursing staff and all clinicians should be made aware of these orders.

COMPARATIVE CPR

The American Heart Association published new guidelines in 2000 for cardiopulmonary resuscitation and emergency cardiovascular care. These guidelines represented significant changes in protocols that should not be immediately extrapolated to veterinary patients. The most significant changes included the incorporation of immediate electrical defibrillation into Basic Life Support (BLS). Previous to this recommendation, BLS included **A**, **B**, **C**, **A**irway, **B**reathing and **C**irculation. **D**efibrillation was included in Advanced Life Support (ALS). The successful impact of rapid electrical defibrillation on survival in patients with cardiopulmonary arrest led to this change in recommendations. The overall impact of this recommendation has been the increased availability and access to automated external defibrillators (AED). This technology allows minimally trained lay rescuers as well as trained rescuers the ability to defibrillate patients with ventricular fibrillation. The emphasis on early defibrillation is based on reports that as many as 70% of people in the United States who experience out of hospital cardiopulmonary arrest are initially in ventricular fibrillation.

Although ventricular fibrillation does occur in dogs and rarely in cats, it is not necessarily the most common rhythm disturbance recognized and is not recognized in the majority of veterinary patients who experience cardiopulmonary arrest.

It has also been found that what would be considered standard drug therapy in veterinary patients, utilizing epinephrine and atropine, has not significantly improved survival in people and therefore these drugs are considered marginal. These drugs would still be considered the cornerstone of therapy for veterinary CPR.

TECHNIQUES

Basic Life Support

In veterinary medicine basic life support (BLS) or basic CPR is still considered the **A**, **B**, **C**'s (**A**irway, **B**reathing, and **C**irculation). Due to the limited access to defibrillators in veterinary practice and the nature of the underlying diseases contributing to cardiopulmonary arrest in veterinary patients, it is unlikely that this will change. It is also important for the veterinary clinician to recognize that many dysrhythmias occur in the critically ill dog and cat. We cannot extrapolate the information that approximately 70% of people who experience cardiopulmonary arrest out of hospital have ventricular fibrillation as their initial rhythm. The common dysrhythmias associated with cardiopulmonary arrest in dogs and cats include, ventricular asystole, pulseless electrical activity (PEA) (formerly known as electrical mechanical dissociation (EMD) and ventricular fibrillation. Therefore the utility of early defibrillation in veterinary patients is unknown unless the patient has documented ventricular fibrillation.

Current recommendations for veterinary BLS include assessing and providing an airway if required, assessing and providing breathing if required and assessing and providing circulation if required.

Airway: Although there are no real changes in the recommendations for this procedure, the priority is to establish an airway. In most cases this is accomplished by per oral endotracheal intubation. Confirmation of correct tube placement is recommended by visual assessment, digital palpation and/or by $ETCO_2$ monitoring. It has been suggested that airway be prioritized below circulation and breathing. In this scenario rather than A, B, C, the priority would be C, A, B. If following this protocol, external thoracic compressions should be started immediately and prior to providing an airway. This recommendation is based on research performed to evaluate bystander (out of hospital) CPR. In some experimental animal models, most notably pigs, it has been shown that animals can be resuscitated from ventricular fibrillation by only performing chest compressions. It has been hypothesized that when performing external chest compressions, enough passive ventilation occurs for the patient to survive. Another important factor is that during ventricular fibrillation, oxygen delivery is dependent on blood flow, not ventilation.

Breathing: The only innovations with breathing have been the use of simultaneous compression ventilation protocols by some clinicians. When utilizing the thoracic pump theory, it has been demonstrated in animal models that cardiac output can be improved by increasing intrathoracic pressure. Conventional external thoracic compressions utilize the cardiac pump theory in combination with interposed respirations. The cardiac pump involves direct compression of the myocardium to promote cardiac output. The thoracic pump utilizes compression of the thoracic cavity to indirectly improve cardiac output by effecting blood flow through the giant vessels. The incorporation of simultaneous ventilations dramatically increases intrathoracic pressure. There are however, potential complications associated with this technique, which include barotrauma and pulmonary contusions. The target for breathing rate should be 15-20 breaths per minute.

Circulation: The circulation component of BLS has not changed significantly and has been discussed in part under the breathing section with reference to simultaneous compression and ventilation protocols. There are currently two theories explaining the mechanisms of cardiac out during external thoracic compressions. The cardiac pump theory suggests that direct compression of the myocardium accounts for the majority of cardiac output. In veterinary patients this would apply in patients with body weights of < 7 kg. In patients with body weights of > 7 kg, the thoracic pump would better explain cardiac output. The latter suggests that compressions of the widest portion of the thorax increase intrathoracic pressures, which indirectly leads to increased cardiac output. This may be combined with simultaneous ventilation, which should further increase intrathoracic pressures. The target for chest compressions should be 100 beats per minute. The use of interposed abdominal compressions during CPR has become more common and has been shown to increase venous return by up to 25%.

Advanced Cardiac Life Support

In veterinary medicine, advanced life support (ALS) has included all procedures outside of BLS. So the pneumonic of **D**, **E**, **F** still applies.

Drugs: Although there are no longer strong recommendations for epinephrine and atropine for therapy of cardiopulmonary arrest in people, these drugs still play a valuable role in veterinary CPR. The most commonly reported dysrhythmias identified during cardiopulmonary arrest in the dogs and cats are bradyarrhythmias, asystole and pulseless electrical activity (PEA) formerly known as electrical mechanical dissociation. Atropine and epinephrine may be useful for management of these dysrhythmias. The current recommendation for the use of epinephrine is using the low dose protocol (0.01–0.02 mg/kg). This protocol calls for the use of the standard concentration of epinephrine (1:1000) diluted 10-fold and administered at a volume of 1 mL/10 kg of body weight. This is compared with the high dose epinephrine protocol which utilizes the same volume administered (1 mL/10 kg) but using the 1:1000 dilution epinephrine straight from the bottle. There is some renewed interest in the use of vasopressin and recent publications have shown some increase in survival in people who have failed conventional medical therapy. Vasopressin can be administered at a dosage of 0.8 U/kg. This equates to approximately 0.5 mL/10 kg of body weight. The advantage of vasopressin may be its performance in the face of hypoxia and acidemia. In addition its mechanism of action is via direct stimulation of receptors in vascular smooth muscle and it does not appear to increase myocardial oxygen consumption. Atropine is still administered at 0.04 mg/kg or approximately 1 mL/10 kg body weight.

Routes of administration that are recommended include intravenous through a central line, intravenous via a peripheral line with bolus to follow, intraosseous administration and intratracheal administration. The drugs that can be safely administered via the intratracheal route can be remembered by the pneumonic **NAVLE** and include **N**aloxone, **A**tropine, **V**asopressin, **L**idocaine, and **E**pinephrine. The doses should be twice the intravenous dose and should be diluted in sterile water.

ECG: In veterinary CPR it is still imperative to know what dysrhythmia is present. Because it is difficult to predict which rhythm is present, intervention and outcome will be dependent on this diagnosis. The most common reported dysthymias include ventricular asystole, PEA and ventricular fibrillation.

Fibrillation control: Defibrillation is prioritized lower and still included in ALS for veterinary patients for two reasons. First and foremost, patients must be in ventricular fibrillation for this intervention to be utilized. Second, it still appears that many veterinary hospitals do not have access to this equipment. The advances in the area of defibrillation are the use of biphasic defibrillators, which may be more effective than the monophasic defibrillators.

Fluid resuscitation: Fluid resuscitation should be a component of CPR. However, aggressive volume expansion should only be utilized if it is suspected that volume depletion has contributed to the cardiopulmonary arrest. Volume overload can have detrimental effects on these patients. An increase in central venous pressure and right sided pressures may lead to reduced coronary perfusion pressures.

MONITORING

Monitoring of patients during CPR is imperative but difficult. Physical examination along with palpation of peripheral pulses, venous blood gas analysis and end tidal capnography are the most reliable tools. Other suggested techniques include the use of a Doppler blood pressure probe on the cornea to evaluate cerebral artery perfusion but this is unreliable in the author's experience. Return of spontaneous ventilation is often a limiting step, as it appears that return to spontaneous circulation occurs more commonly. The frequent cessation of external thoracic compressions in order to examine the ECG or auscultate the thorax may lead to decreased success.

POST-RESUSCITATIVE CARE

Due to poor survival rates, it is often unexpected that post-resuscitative care is required. It is however imperative that the clinician anticipate survival so this care can be provided immediately. If post-resuscitative care cannot be provided then the CPR was wasted. Post-resuscitative care is primarily symptomatic and is dependent on close monitoring and excellent nursing care. Oxygen supplementation should be considered in all of these patients and ventilatory support may also be required. Fluid therapy should be continued as required and inotropic and pressor therapy may be indicated to maintain mean arterial pressures. Neurologic dysfunction may be common following resuscitation and infusion of mannitol at 0.5 to 1 g/kg over 30 minutes may help treat cerebral edema and has free radical scavenging properties. It has also been demonstrated that hyperglycemia may have a negative impact on outcome and therefore should be monitored. Due to the lack of evidence for their use, corticosteroids should be avoided. If possible prognosis should not be based on neurologic signs within the first 24 to 48 hours due to the possibility of significant change. Nutritional support via feeding tubes or total parenteral nutrition should be provided if patients have not returned to reasonable function within 48 to 72 hours.

EMERGENCY MANAGEMENT OF THE PATIENT WITH HEATSTROKE

Michael Schaer, DVM, Diplomate ACVIM & ACVECC
College of Veterinary Medicine
University of Florida, Gainesville, FL

Heatstroke occurs when the elevation of the body's temperature, due to environmental heat stress, exceeds the cooling capacity of compensatory mechanisms. With heatstroke the cells literally cook. This causes thermal damage to the hypothalamic thermoregulatory centers that will further elevate the body temperature. This can be complicated by disseminated intravascular coagulation initiated by disrupted vascular endothelium, which compounds the global pathology. Classically, central nervous system dysfunction is always evident while markedly elevated liver enzyme levels are typical clinicopathologic abnormalities.

There are two main types of heatstroke: classic and exertional. Classic heatstroke is associated with impaired compensatory mechanisms. It usually affects elderly or disabled humans who experience prolonged exposure to hot and humid conditions. It is of gradual onset over a period of hours to days.

Exertional heatstroke occurs in individuals with normal compensatory mechanisms who are exposed to overwhelming heat stress. Its clinical features include: 1) rapid onset CNS dysfunction associated with stupor, delirium, focal deficits, and seizures, 2) history of exposure, 3) warm skin, 4) tachypnea, often from edema or hemorrhage, and 5) vomiting and diarrhea. Gastrointestinal hemorrhage can result from disseminated intravascular coagulation (DIC).

PATHOPHYSIOLOGY

Acute Phase Response

The body has a protective acute phase response to heat stress that is a coordinated reaction that involves endothelial cells, leukocytes, and epithelial cells that protect against tissue injury and promote repair. The interleukin-6 produced during heat stress modulates local and systemic acute inflammation responses by controlling the levels of inflammatory cytokines. Interleukin-6 also stimulates hepatic production of anti-inflammatory acute-phase proteins, which inhibit the production of reactive oxygen species and the release of proteolytic enzymes from activated leukocytes. Other acute-phase proteins stimulate endothelial-cell adhesion, proliferation, and angiogenesis, thus contributing to repair and healing.

Experimental heatstroke models show local and system insults associated with heat stress, such as splanchnic hypoperfusion and altered immunologic and barrier functions of the intestines. This allows for leakage of endotoxins, increased production of inflammatory cytokines, and the release of endothelial vasoactive factors such as nitric oxide and endothelins.

Heatstroke and its progression to multiple organ dysfunction syndrome (MODS) are due to a complex interaction between hypocirculatory function, the direct cytotoxicity of heat, and the inflammatory and coagulation responses of the host. These even lead to altered blood flow in the microcirculation which results in injury to the vascular endothelium and tissues.

Cytokines

The inflammatory cytokines that are elevated include tumor necrosis factor-α (TNFα), interleukin IP, and interferon-gamma. The anti-inflammatory cytokines that are elevated include interleukin-6, soluble TNF receptors p55 and p75, and interleukin-10. An imbalance between the two types of cytokines may result in either inflammation-associated injury or refractory immunosuppression.

Coagulation-Cell Injury and Endothelial-Cell Injury

Endothelial cell injury and diffuse microvascular thrombosis are prominent features of heatstroke. Therefore, DIC and alterations in the vascular endothelium may be important pathologic mechanisms in heatstroke. Normalization of the core temperature inhibits fibrinolysis but not the coagulation aspects of DIC.

The hemodynamic changes are characterized as a high output vasodilated state. The patient might not be significantly volume depleted, but instead have a near-normal volume that is physiologically shunted to the periphery. The central venous pressure and left ventricular filling pressure are usually midrange to low and rise upon cooling. Hypotension is common and is usually not a consequence to fluid depletion but rather to high output heart failure.

In humans, certain cardiopulmonary changes occur in heatstroke. Electrocardiographic abnormalities include ST depression, T inversion, QT prolongation, and intraventricular conduction delays. These changes are attributed to myocardial hemorrhage which can resolve and allow the EKG to return to normal. Pulmonary edema is an occasional complication caused by thermal injury to vascular endothelium, myocardial dysfunction, return of large volumes of plasma to the central circulation after cooling, cutaneous vasoconstriction, and the adult respiratory distress syndrome.

Thermal toxicity can involve the brain to cause brain cell death, cerebral edema, and local hemorrhage to lead to stupor and coma. Early changes can be reversed with prompt treatment.

Acute renal failure affects 35% of human cases. Contributing factors include thermal injury, hypotension, and shock from cardiovascular collapse and rhabdomyolysis. It is therapeutically important to promote continuous urine flow with intravenous fluids, mannitol, and furosemide, if necessary.

The clinical pathology changes can be extensive and include marked elevations in the liver enzymes (alanine aminotransferase [ALT], aspartate aminotransferase [AST], lactate dehydrogenase [LDH]) and creatine kinase, and decreased PaO_2 with a mixed metabolic acidosis/respiratory alkalosis. The urinalysis changes often include myoglobinuria, pigment casts from rhabdomyolysis, RBCs, and protein. The serum calcium level is usually normal. It might decrease initially due to calcium deposition in injured muscle and then rebound 2 to 3 days later to hypercalcemia after the calcium deposits dissolve.

The hemogram changes can include leukocytosis, hemoconcentration, and anemia if a hemorrhagic diathesis occurs. Disseminated intravascular coagulation occurs commonly with severe heatstroke and is associated with prolonged prothrombin time (PT)/partial thromboplastin time (PTT), hypofibrinogenemia, thrombocytopenia, and positive fibrin split products. It is caused by thermal activation of platelets and clotting factors, heat-induced liver failure and impaired coagulation factor synthesis, and activation of the clotting cascade by vascular endothelial damage and generalized cell necrosis. DIC will increase mortality associated with heatstroke. Heparin therapy is controversial, but has been associated with recovery.

The most serious complication of heatstroke involves MODS. These include encephalopathy, rhabdomyolysis, acute renal failure, hepatocellular injury, intestinal ischemia or infarction, pancreatic injury, and hemorrhagic complications, especially DIC.

TREATMENT

The therapeutic outcome with heatstroke patients is directly related to the duration of exposure of tissues to high temperatures. Immediate cooling is paramount and should begin at the same time as general stabilization measures are undertaken. Field cooling may be accomplished by splashing or spraying water over the patient, while using any means of obtaining airflow. Once the patient has arrived at the hospital, other cooling measures can commence. Ice bath immersion has recently been viewed with skepticism because conduction is a fairly inefficient mode of heat transfer compared with evaporation/convection. Furthermore, transfer of heat from the body core to the environment is dependent on the conductivity of the skin and subcutaneous tissues, which in turn depends on blood flow. Ice water immersion rapidly drops skin temperature, but the resulting vasoconstriction causes the skin and subcutaneous tissues to behave as an insulator, blocking heat transfer from the core. Lowered skin temperatures also result in shivering, which generates heat and further limits cooling. It is difficult to maintain monitoring devices on immersed patients.

The preferred cooling method involves the use of a lukewarm water spray along with fans. This method is not only practical, but it minimizes shivering, vasoconstriction, and discomfort. In dogs and cats, the cooling treatment process should be discontinued when the body temperature reaches 103°F in order to avoid iatrogenic hypothermia.

Other cooling methods include 1) cold IV lines and oxygen, which contribute little to heat transfer, and 2) high frequency jet ventilation, which increases evaporative heat loss from the respiratory tract by increased minute ventilation through the upper airway, and ice water gastric lavage. Ice water enemas are thought to be of little use and theoretically can cause water intoxication. ***Isopropyl alcohol soaks risk skin absorption and toxicity and are no longer considered in pediatric humans.*** The use of antipyretics (aspirin, acetaminophen) is irrational because these function through lowering of the hypothalamic thermoregulatory set point, which is inoperative in heatstroke.

Fluid therapy for the heatstroke patient should be adjusted to the patient's pathophysiologic status. If heat stroke occurred rapidly over a relatively short period of time just prior to its being presented for veterinary care, there will hardly be any significant dehydration. In such cases, the patient's blood pressure is the primary concern and crystalloid fluid therapy should be used according to its blood volume status. Hypotensive patients should receive a volume expanding dose of isotonic fluids such as lactated or acetated Ringer's. Although one whole blood volume of fluids (70–90 mL/kg for a dog and 35-40 mL/kg for a cat given over the first hour) is generally recommended for the treatment of a hypotensive crisis, close patient monitoring for intravascular fluid overload should be done every 15 minutes during that rapid phase of fluid administration. The heat stroke patient might be particularly predisposed to cardiopulmonary dysfunction thus making it prone to developing pulmonary edema from an excessive fluid delivery rate. Persistent hypotension after the administration of IV crystalloid will call for treatment with a colloid solution such as Hetastarch. Failure to hemodynamically stabilize the patient after this will call for vasopressor drug treatment using either dobutamine, dopamine or vasopressin.

Urine volume must be closely monitored because oliguric or polyuric acute renal failure can be a significant complicating factor. In the case of oliguria, attempts to improve urine output with the administration of furosemide (1–2 mg/kg IV) should be done because further fluid therapy will be more complicated if anuria occurs. In such cases, the dose of IV fluids will be measured against the measured urine output, insensible water losses (13–20 mL/kg/24 hours), and any other ongoing fluid losses as might occur with vomiting or diarrhea.

Patient monitoring for the most severe patient should be as physiologic as possible by using information that can be obtained with central venous pressure, arterial blood pressure, and urine output measurements. This will allow the clinician to alter the treatment according to the changing needs of the patient. A central intravenous line will facilitate the administration of medication as well as allow ready access for blood sample collections.

Broad-spectrum antibiotics are commonly provided to veterinary patients with heatstroke in order to cover for the transluminal migration of intestinal bacteria that can enter the systemic circulation subsequent to the breakdown of the bowel mucosal barrier. Broad-spectrum coverage is recommended because severe heat stroke and sepsis commonly coexist because of the above mechanism.

Alpha agonists should be avoided initially because they promote peripheral vasoconstriction that will prevent cooling. They can also cause further ischemia to already impaired organs such as the kidney or the liver. Dopamine and/or dobutamine, however, may be indicated for refractory hypotension.

Heparin is recommended for severe heatstroke. Plasma can also be given if abnormal bleeding is present. At first, an initial bolus dose of 75 to 100 units/kg can be administered intravenously. This is followed by subsequent doses of 75 to 100 units/kg every 8 hours delivered by slow intravenous infusion over each 8-hour period. If treatment is successful, the patient and its coagulation parameters should show improvement after 24 hours after which time the heparin dosage is tapered and discontinued over the subsequent 24-hour period.

PROGNOSIS

Morbidity and motility are directly related to the peak temperature and to the duration of time the elevated temperature persists. A delay in treatment for two hours or more may result in a 70% chance of death in humans. Prolonged coma of greater than four hours is also a poor prognostic factor.

GASPING CAT – APPROACH TO THE DYSPNEIC FELINE

Michael Schaer, DVM, Dipl. ACVIM & ACVECC
College of Veterinary Medicine
University of Florida, Gainesville, FL

Thoracic disease in the cat can present as one of a multitude of disorders. Many of the problems are treatable pending a definitive diagnosis, while others are classified as non-treatable. It is important for the practitioner to accurately identify the exact disease process in order to implement what might end up to be life-saving treatment. On the other hand, the early recognition of a non-treatable disease in a dyspneic patient can avoid protracted suffering to the cat and excess expense to the client.

Dyspnea and tachypnea are the most characteristic signs of feline pulmonary and pleural diseases. Although coughing is a sign frequently associated with tracheal and bronchial disorders, the clinician should be aware that most feline pulmonary and pleural disorders are not associated with coughing. Because the dyspneic cat is often in critical status, the primary clinical objective is to expediently diagnose the cause and simultaneously provide supportive treatment.

The etiologies of respiratory embarrassment can involve lesions anywhere along the respiratory tract, pleural space, or heart. Therefore, it behooves the clinician to obtain a complete history and perform a detailed physical examination to accurately localize the primary lesion. Emergency situations might initially require an abbreviated history and physical followed by a more detailed study following the patient's stabilization.

The diagnosis of most thoracic diseases in the cat usually requires the use of diagnostic aids. Depending on the problem at hand, such tests might include: hemograms, serum biochemistry determinations, cytology and culture of respiratory secretions, serology, electrocardiography, tissue biopsy, and thoracic radiography. To avoid compounding the stress to the dyspneic cat, certain diagnostic procedures might have to await the clinical response to symptomatic emergency therapy in order to avoid iatrogenic complications. The criteria for classifying thoracic disease will vary among the internist, radiologist and pathologist.

Table 1. Characteristics of Some Disorders Causing Pulmonary Alveolar Infiltrates in the Cat

Disease	Predisposing or Direct Cause	Other Diagnostic Findings	Treatment Principles	Prognosis
Bacterial pneumonia	1. Viral respiratory infection 2. Aspiration 3. Primary/idiopathic	- Fever - Leukocytosis - Radiographic lobar involvement; ventral common - Tracheal wash cytology: WBCs, bacteria	1. Maintain hydration with parenteral fluids 2. Provide O_2 3. Antibiotics 4. Bronchodilating drugs	Fair to guarded
Chemical pneumonitis	1. Smoke inhalation 2, Aspiration of oral or gastric secretions	- History & physical findings obvious with smoke inhalation - Aspiration commonly occurs with altered consciousness or iatrogenic - Bacterial pneumonia commonly complicates	1. Assure patent upper airway 2. Broad spectrum antibiotics 3. Bronchodilating drugs	Fair to guarded
Cardiogenic pulmonary edema	1. Cardiomyopathy 2. Hyperthyroid-induced myocardial hypertrophy 3. Congenital 4. Acquired valvular disorders	- Characteristic auscultable findings: murmurs, gallop rhythm, arrhythmias - Radiographic cardiomegaly with pleural effusion or alveolar infiltrate - EKG & echocardiographic Changes	1. Provide O_2 2. Furosemide 3. Specific cardiac drugs depending on exact pathology	Guarded to grave
Noncardiogenic (neurogenic) pulmonary edema	1. Electrocution 2. Post seizure	- Electrocution: acute onset, oral burn, dorsocaudal radiographic pulmonary alveolar infiltrate - Post seizure	1. Furosemide 2. Provide O_2 cage 3. Avoid dehydration	Guarded to good

Table 2. Characteristics of Selected Feline Interstitial Lung Disease

Disease	Cause	Helpful Ancillary Clinical Findings	Treatment	Prognosis
Interstitial edema	1. Cardiomyopathy, & other causes of congestive heart failure 2. Noncardiogenic 1. Hypoalbuminemia 2. IV fluid overload 3. Electrocution 4. Viral infections 5. Toxic inhalants	Gallop rhythm, echo- & electrocardiographic abnormalities, cardiomegaly History of exposure to toxic inhalants, viral infections, iatrogenic fluid overload, electric cords	1. Diuretics, O_2, specific cardiac drugs such as digoxin or propranolol depending on type of cardiac pathology 2. Diuretics, O_2, removal of insulting agent, theophylline	(1) Guarded to grave (2) Good to poor depending on associated cause
Interstitial pneumonia	Viral respiratory disease	Fever, nasal discharge, sneezing, conjunctivitis, oral ulcerations, history of exposure to infected cats, viral isolation	Supportive: maintain hydration & nutrition, antibiotics for 2° bacterial complications	Good to fair
Granulomatous disease	Systemic mycoses, toxoplasmosis, irritating inhalants, immune-mediated disease	Knowledge of geographic origin where mycotic disease prevails; dietary & environmental history; presence of other coexisting organ abnormalities; serology; tissue biopsy	Toxoplasmosis:pyrimethamine & sulfadiazine; clindamycin Histoplasmosis & blastomycosis:- Itraconazole, amphotericin B Immune-mediated disease: immunosuppressants	Fair to grave
Pulmonary fibrosis	Healing phase of several disease processes; sometimes idiopathic; old age change	History of prior pulmonary inflammatory disease; normal hematologic & cytologic test results; sometimes history reveals chronic coughing; absence of other physical abnormalities	Bronchodilating drugs such as theophylline or aminophylline; occasional short-term use of gluco-corticoids. No reversal nor cure for pulmonary fibrosis.	Fair to poor
Metastatic lung neoplasia	Extrapulmonary source of malignant neoplasia, ie, mammary adenocarcinoma	Coughing is rare; location of primary source of neoplasia via physical exam, radiography, or surgery; tissue biopsy with histopathologic confirmation; needle aspiration cytology	Chemotherapy; surgical removal of primary tumor if indicated	Usually grave
Primary lung neoplasia	Example: bronchogenic carcinoma	Physical exam might reveal muffled chest sounds on involved side; radiography strongly suspicious; neoplastic cells on needle aspirate or surgical biopsy specimens; cough is rare unless there is bronchial impingement	Chemotherapy, surgical removal	Usually grave
Lung worms	Aleurostrongylosis	Mixed pattern on radiographs; findings of larval forms on fresh fecal smears & Behrman technique; coughing a common associated finding; eosinophilia on hemogram	(a) Levamizole - 20 to 30 mg/kg once every other day for five treatments (b) Fenbendazole 50 mg/kg/d x 3 d	Good
Lung fluke	*Paragonimus kellicotti*	Radiographs: solid or cavitated, circumscribed densities usually in caudal lobes; coughing common, fluke eggs on fecal, eosinophilia	(a) Albendazole- 50 mg/kg/d minimum of 14 days (b) Fenbendazole 50 mg/kg/d x 10 d (c) Praziquantel 25 mg/kg Q 8 h x 2 d	Good to fair
Heartworms	Dirofilaria immitis	Diffuse interstitial infiltrate; pulmonary artery enlargement; right heart enlargement; eosinophilia	Author does not recommend adulticide treatment; treat symptomatically with glucocorticoids & for heart failure (if present)	Guarded

Table 3. A Clinical Description of the Causes of Pleural Effusion in the Cat

Cause	Associated Physical Findings	Associated Clinical Findings	Fluid Type and Characteristics	Treatment	Prognosis
Congestive cardiomyopathy	- Dyspnea - Muffled chest sounds - Sometimes heart murmurs - Cardiac gallop rhythm - Rarely ascites - Occasionally aortic thrombo-embolism	(1) Characteristic electrocardiographic abnormalities (2) Oftentimes mild BUN elevations & moderate liver serum enzyme elevations (3) Radiographically generalized cardiomegaly with pulmonary interstitial or alveolar pattern along with pleural effusion	(1) Obstructive effusion (2) Serous, pseudochylous, or serosanguineous (3) Modified transudate (4) Cytology: initially mainly RBC's & lymphocytes with smaller numbers of neutrophils, macrophages, & mesothelial cells	(1) Removal of fluid by thoracentesis (2) O_2 (3) Diuretics (4) Digoxin (5) Taurine 500 mg bid	Guarded to grave
Lymphosarcoma	- Dyspnea - Muffled chest sounds (sometimes mainly anteriorly) - Noncompressible anterior thorax - Sometimes fever - Occasionally other organ involvement	(1) Sometimes anemia (2) Rarely lymphocytosis with anaplasia (3) (+) FeLV (4) Radiographically: anterior mediastinal mass causing tracheal elevation & posterior displacement of the heart (5) Ocular fundoscopic changes occasionally (6) Neoplastic lymphocytes on aspirate cytology of the mass (7) Rarely hypercalcemia	(1) Obstructive effusion (2) Serous or serosanguineous (3) Modified transudate or exudate (4) Cytology: anaplastic lymphocytes with mixture of RBC, mesothelial cells, macrophages & neutrophils	(1)Thoracocentesis (2) Chemotherapy	Guarded to grave
Pyothorax	- Dyspnea - Fever - Sometimes dehydration - Muffled chest sounds	(1) Leukocytosis with left shift (2) Radiographically: no cardiomegaly or thoracic masses; pleural thickening (3) Bacterial growth on culture (4) Possible restrictive lung disease	(1) Septic inflammatory (2) Purulent or sanguinopurulent (3) Pure exudate (4) Cytology: many neutrophils containing bacteria, free bacteria, toxic neutrophils, mononuclear cells	(1) Thoracocentesis (2) Thoracic lavage (3) Antibiotics	- Good to poor - Lung Abscess & chronic pleuritis are possible sequele
Infectious feline peritonitis – "wet-form"	- Dyspnea - Fever - Muffled chest sounds - Occasionally Corneal precipitates or fibrinous uveitis - Occasionally bilateral "lumpy" renomegaly	(1) Mature neutrophilia (2) Hyperglobulinemia with polyclonal gammopathy (3) FIP titer undependable & nonspecific	(1) Pyogranulomatous (2) Straw-colored, viscous, rarely chylous (3) Cytology: moderate numbers of neutrophils, RBC, plasma cells, macrophages, lymphocytes, granular background	(1) Thoracocentesis (2) Supportive	Grave

Table 3. Continued.

Intravenous fluid overload	Sudden onset of dyspnea in cats being Rx with IV fluids; muffled chest sounds; occasionally edema	(1) Possible occult Cardiomyopathy made apparent with fluid overload (2) Possible coexisting anemia or hypoalbuminemia predisposing to fluid overload (3) Sometimes purely iatrogenic from over-zealous treatment	(1) Pure transudate (2) Clear (3) Almost acellular on cytology	(1) Thoracocentesis (2) Judicious use Of diuretics (3) Give plasma or whole blood transfusion for hypoalbuminemia & anemia, respectively	Good if no serious underlying cause is present
Acute trauma or bleeding disorders	- Dyspnea - Variable muffled chest sounds - Other signs of trauma or sites or hemorrhage	(1) Trauma- variable (2) Coagulopathy – abnormalbleeding test parameters; ie, prolonged PT, PTT, low platelet count (2) Radiographs in trauma often denote fractured ribs & pulmonary contusion pattern (3) Exposure to anticoagulant drugs or poisons	(1) Blood red; defibrinated (2) RBC & WBC proportions similar to blood	Trauma - depending on injury; usually conservative rest in the absence of other serious problems. Coagulopathy - (a) whole blood transfusion if severe (b) cryoprecipitates (c) vitamin K_1, for warfarin intox.	Usually good
True chylothorax	- Dyspnea - Muffled chest sounds - Occasional cough	(1) Possible history of prior chest trauma (2) Occasional lymphopenia (3) Other causes include heart failure, heart worms, neoplasia	(1) Milky white (2) Cytology: normal lymphocytes, small # of RBC, smudge cells (3) Orange staining Chylomicrons with Sudan III (4) Elevated triglycerides	Surgical ligation of thoracic duct & anomalous lymphatics	Fair to guarded
Thoracic carcinomas or sarcomas	- Dyspnea - Muffled chest sounds - Possible location of extrathoracic source of neoplasia	(1) Radiographs: demonstration of neoplasm (2) Tissue biopsy confirmation if extrathoracic source is accessible	(1) Usually serosanguineous (2) Obstructive or inflammatory (3) Cytology: RBC, mononuclear cells, mesothelial cells, anaplastic cells (variable presence)	(1) Thoracocentesis (2) Surgical removal if there is solitary mass (3) Chemotherapy	Guarded to grave

FLUID THERAPY FOR CRITICALLY ILL DOGS AND CATS

Michael Schaer, DVM, Dipl. ACVIM & ACVECC
College of Veterinary Medicine
University of Florida, Gainesville, FL

Fluid therapy in clinical medicine is used to fulfill the following objectives: (1) to replace dehydration deficits, (2) to maintain normal hydration, (3) to replace essential electrolytes and nutrients, and (4) to serve as a vehicle for the infusions of certain intravenous medications. Except for the urgency of treatment, the same objectives apply in the critically ill animal. The methods for providing fluids often influence the eventual outcome of the case. The clinician and staff, therefore, should familiarize themselves with the pathophysiology of the diseases they are treating and how these conditions relate to the various types of fluids that are available for general use.

FLUID VOLUME REPLACEMENT

The animal requires fluids for (1) rehydration, (2) maintenance, (3) replacement of insensible loss volumes, and (4) replacement of ongoing loss volumes. Clinically, the amount of fluid needed to correct dehydration deficits can be assessed from the degree of skin turgor, capillary refill time, and pulse rate and quality. The degree of dehydration ranges from 5% to 12%. Skin turgor assessment can sometimes be misleading in the obese animal, because adipose tissue replaces subcutaneous interstitial water and maintains elasticity despite negative water balance. Also, old, cachectic patients that have lost skin resiliency may give a false impression of marked dehydration. To clarify the diagnosis in such questionable situations, clinicians can check for the elevated packed red cell volume and plasma total solids that accompany the hemoconcentration caused by volume depletion. Discretion should be used when interpreting these clinicopathologic parameters, because lab values in an anemic animal with concomitant hypoproteinemia may seem normal even if the animal is dehydrated.

The volume of fluid needed to correct dehydration is calculated from either of the following formulas:

- Volume (mL) of fluid needed = % dehydration x body weight (lb) x 500
- Volume (mL) of fluid needed = % dehydration x body weight (kg) x 1000

The maintenance volume is that amount normally required in a 24-hour period by a well-hydrated patient. Taking insensible fluid loss into consideration, which amounts to 13 to 20 mL/kg/day, the 24-hour maintenance volume for a dog or cat whose urine output is normal is approximately 50 to 60 mL/kg (25 to 30 mL/lb) per day. The total 24-hour fluid requirement for the dehydrated animal is the sum of maintenance volume and volume required to correct dehydration.

The initial rate and route of fluid delivery depend on the patient's status. Mildly to moderately dehydrated small dogs and cats that require short-term fluid treatment can be adequately managed with subcutaneous fluids.

Any severely (>10%) dehydrated patient should initially receive fluids intravenously. Because of the accompanying vasocollapse, medications injected subcutaneously may not be adequately absorbed into the systemic circulation. For the mildly to moderately hypovolemic patient, it is recommended that one fourth to one half of the estimated dehydration deficit be replaced over the first 2 to 4 hours with the remaining dehydration deficit and maintenance isotonic volumes administered over the subsequent 20- to 22-hour period. The amount of subsequent fluid infusion will depend on the patient's response to treatment.

Exceptions to the recommended maintenance doses of fluids occur under the following circumstances:

- **Oliguria and anuria.** After dehydration deficits are replaced, the patient's maintenance needs depend on urinary output, which should be estimated or quantitated. Providing full normal maintenance fluid volumes to oliguric and anuric patients can lead to fatal pulmonary edema or pleural effusion because of iatrogenic intravascular fluid overload. Specific treatment for low output renal failure is provided in the next section.
- **Polyuria.** Polyuric animals require fluid volumes in ...excess of normal maintenance needs. Failure to provide these volumes can result in a sustained negative water balance if the patient is unable to drink. The maintenance needs for polyuria consist of exact urinary losses plus insensible and ongoing losses. Assurance of adequate treatment is made by weighing the patient each day as well as by assessing the physical and laboratory parameters for hydration. An acute loss of 1 kg of body weight suggests a 1 L fluid deficit.
- **Rapid internal shifts of fluid**, which can occur in pancreatitis, extensive burns, enteritis, and gastrointestinal obstructions. In these conditions, the fluid needs of the patient will exceed the usual maintenance volumes by as much as three times.

The assessment of the animal's fluid requirements must always be made within the pathophysiologic context.

ANEMIA

Intravenous fluids are sometimes used excessively in the anemic patient when the decrease in red blood cell mass is misinterpreted as total blood volume depletion, when in fact the plasma volume might even be expanded. To compensate for decreased tissue oxygen delivery, the heart rate increases, and if these patients are subjected to large fluid volumes over a short period of time, pulmonary edema can occur.

Anemic cats in particular are susceptible to intravenous overload from crystalloid infusions. The dehydration deficit and maintenance fluid volumes should be gradually replaced over a 24-hour period with an isotonic crystalloid solution, while fresh whole blood is used to replace the red blood cells. The volume of whole blood infused should be considered when calculating the volume of crystalloid for infusion.

EXTRACELLULAR FLUID VOLUME EXCESS

This condition is associated with an increase in total body salt and water and occurs in a variety of clinical settings including congestive heart failure, glomerulopathies, liver fibrosis, and protein-losing enteropathy. These conditions are associated with a decrease in "effective arterial volume," which stimulates the renin-angiotensin-aldosterone cycle and the release of antidiuretic hormones to promote renal salt and water retention, respectively. Because of increased venous pressure from heart failure and cirrhosis or because of decreased plasma oncotic pressure associated with hypoalbuminemia, the retained salt and water move into the interstitial and other body spaces, causing edema, ascites, or pleural effusion. Hypervolemia amounting to 20% to 30% in water excess can cause pulmonary edema.

Patients with any of these conditions are extremely sensitive to intravenous overload with crystalloid solutions. Treatment should be directed toward improving the underlying primary pathologic process. Fresh or fresh frozen plasma should be used to volume expand animals with hypoalbuminemia, although in glomerulopathies and protein-losing enteropathy (PLE), beneficial effects are usually temporary at best because of continued protein losses especially with PLE.

Heart failure patients receiving intravenous fluids should be closely observed for weight gain and respiratory distress caused by intravascular fluid overload. A rapid respiratory rate will often be the earliest sign of overload therefore calling for close patient observation. Under optimal conditions, monitoring of central venous and pulmonary wedge pressures is helpful for avoiding this potentially fatal complication. The reader is referred to other sources for details regarding these techniques.

When parenteral fluid therapy is indicated in the cardiac patient, solutions containing little or no sodium are given after dehydration and hypovolemia are corrected with isotonic solutions. Either 0.45% saline or D-5-W can be used. Efforts should be made to avoid hypokalemia by adding potassium chloride solution to the fluids at a dose of 7 to 10 mEq/250 mL. Periodic monitoring of serum electrolytes is necessary for accurate treatment adjustments.

HYPOVOLEMIC SHOCK

The loss of 30% to 40% of intravascular volume will cause severe hypovolemia and hypotension. Cardiac arrest occurs when 50% to 60% of blood volume is lost.

Isotonic crystalloid solutions [saline 0.9% (NS), acetated Ringer's or lactated Ringer's solution (LRS)] are the most commonly used replacement fluids because they are usually effective, readily available, easily administered, and relatively inexpensive. Severely hypotensive patients might require at least one whole blood volume of replacement fluids during the first hour of treatment. Initial rapid infusion for dogs should be 20 to 40 mL/kg IV (one half this amount for cats) for 15 minutes, followed by 60 mL/kg (dogs) or 20 mL/kg (cats) administered over one hour. This loading volume is followed by administration of maintenance fluids at a rate of 10 to 12 mL/kg/hr for dogs and 5 to 6 mL/kg/hr for cats. The patient's heart and respiratory rates and urine volume are monitored every 15 minutes during vascular volume resuscitation. Any signs of fluid overload necessitate prompt decreases in fluid delivery and consideration of diuretic therapy. Optimally, central venous or pulmonary arterial wedge pressure determinations should be used to monitor the patient's hemodynamic status.

This particular fluid regimen is especially useful for treating dogs and cats with trauma-induced peracute blood loss. It has also been proved efficacious for treating other conditions in which plasma volume is depleted rapidly, such as the canine hemorrhagic gastroenteritis (HGE) syndrome. After volume loading an HGE patient with crystalloid solution, the plasma proteins will decrease substantially. In most cases this will begin to correct itself after the first 24-hour period of treatment.

Vigorous fluid administration can cause significant problems: a rapid increase in hydrostatic pressure, dislodgement of previously formed hemostatic plugs, reduced blood viscosity, and dilution of oxygen carrying capacity and coagulation factors.

In a setting of traumatic hemorrhage restoring the systolic blood pressure to no more than 60 mmHg can help avoid dislodgement of any clots that have formed.

Any coexisting pulmonary contusions, cardiogenic shock, and hypoproteinemia requires cautious delivery of IV crystalloid solutions.

VOMITING

Vomiting is the principle sign of gastric disease, but it can also accompany disorders of the small or large bowel, liver, and pancreas, as well as disorders occurring outside of the digestive system. Vomiting can deplete the body of a substantial volume of fluids and electrolytes. The specific types of electrolyte deficiencies and acid-base abnormalities depend on the location of the primary disorder. Vomiting caused by pyloric outflow obstructions typically can lead to dehydration, metabolic alkalosis, hypochloremia, hypokalemia, and hyponatremia. NS supplemented with potassium chloride (3 to 10 mEq/kg_{BW} every 24 hours) is the fluid of choice.

Fluid losses through vomiting associated with systemic illness or intestinal disease are best replaced with lactated or acetated Ringer's solutions. The patient's serum electrolyte status should be monitored and corrected when indicated.

GASTRIC DILATATION-VOLVULUS (GDV)

The GDV complex causes hypovolemic shock as well as gastric sequestration of fluids and electrolytes.

Although the hypovolemia can cause tissue hypoxia and eventually metabolic acidosis, there are several instances in which the gastric hydrogen and chloride ion sequestration can offset the acidosis and perhaps even cause a metabolic alkalosis. Although most dogs with GDV are initially volume resuscitated with LRS, their acid-base parameters should be monitored if possible in order to detect any need for a change in fluid type.

OLIGURIC AND ANURIC RENAL FAILURE

The urine output of all critically ill patients should be monitored, especially during periods of intensive fluid therapy. Fortunately, many oliguric patients will begin producing urine after they receive one half of their estimated dehydration deficit values during the first one to two hours of treatment. If urine production is inadequate, the following protocol is recommended:

- Insert an indwelling urethral catheter and empty the urinary bladder of any residual urine.
- Administer the calculated dehydration deficit fluid volume over the first two to four hours of treatment.
- Once rehydration has occurred, administer furosemide (4 mg/kg IV push) and/or mannitol (0.5 g/kg IV) over a 10-minute period.
- If no urine flow occurs, readminister furosemide (8 mg/kg IV push) or administer dopamine (1 to 2 µg/kg/min IV).
- If oliguria or anuria persists, the amount of fluids infused per day will consist of the sum of the measured urine output, the insensible water loss (13–20 mL/kg/day), and the extra losses caused by vomiting or diarrhea. Peritoneal dialysis will be required to rid the body of uremic toxins.

Plasma volume expansion should be accomplished with LRS or NS; the latter is preferred if hyponatremia is present. Maintenance fluids can initially consist of Ringer's lactate or acetate but can eventually be reduced in concentration to one-half strength in the absence of any renal sodium-losing disorder.

DIARRHEA

The fluid deficit from massive diarrhea can be efficiently corrected with LRS because it resembles the type of fluid lost, is readily available, and provides uniformly good results. In markedly hypotensive patients, the intravenous fluids should be given as described previously (see Hypovolemic Shock).

HYPEROSMOLAR CONDITIONS

The common causes of extreme hyperosmolality in the dog and cat include hyperosmolar nonketotic diabetes mellitus, hypernatremia associated with water deprivation in diabetes insipidus patients, and essential hypernatremia (in dogs). In hyperosmolar diabetes, dehydration is easily detectable through skin turgor evaluation; in the latter two conditions, the interstitial water is often retained because of a shift of fluid from the intracellular space, thereby allowing for normal skin turgor. Eventually, however, the subcutaneous water will become depleted. In each of these conditions, hypovolemia can be life-threatening.

It would seem logical that a hypotonic solution such as D-5-W (252 mOsm/L) would be the fluid of choice; however, this solution rapidly exits from the intravascular space (two thirds of the infused volume exits within the first hour), and thereby does little to expand the intravascular fluid space. The preferred initial fluid, therefore, is NS because of its isotonicity, its tendency to persist within the intravascular space for a reasonable length of time, and its hypotonicity relative to the patient's hyperosmolar plasma. After adequate plasma space resuscitation, the infusion can be changed to 0.45% saline with or without 2.5% dextrose added.

In marked hypernatremia (serum Na^+ > 165 mEq/L), the goal of treatment is reduction of the serum sodium level by 0.5 to 1.0 mEq/L per hour, replenishing one half of the water deficit in 12 to 24 hours and the remainder in another 24 hours. This gradual water replacement will prevent cerebral edema and death, which can be caused by too rapid correction of the serum sodium level.

HYPOTONIC DISORDERS

A hypotonic disorder is one in which the serum osmolality and sodium levels are reduced in parallel. Clinically significant hyponatremia is most often due to an inability to excrete a maximally dilute urine.

The goal of treatment in hyponatremia is to correct body water osmolality and restore cell volume by raising the sodium-to-water ratio of extracellular fluid. Acute hyponatremia occurs when the decline in serum sodium exceeds 0.5 mEq/L/hr. When levels fall below 120 mEq/L, with associated brain dysfunction, the condition should be treated immediately. Hypertonic saline (3% or 5% is administered at a rate of at least 1 mEq/L/hr to replace sodium.

Chronic hyponatremia is more common than the acute form and occurs when the rate of decline is less than 0.5 mEq/L/hr. Slow correction, essential for preventing central pontine myelinosis, is accomplished by administering NS and furosemide at a rate of less than 0.5 mEq/L/hr.

HYPERCALCEMIA

Many patients with hypercalcemia are volume depleted. Initially, NS should be infused to normalize intravascular volume. Because the renal excretions of sodium and calcium are linked, a forced saline diuresis using furosemide and isotonic saline will accelerate calciuresis. Close monitoring of serum electrolyte levels, especially potassium, is essential to detect and correct possible hypokalemia. All patients receiving rapid saline diuresis should be monitored for signs of intravascular fluid overload.

PULMONARY CONTUSIONS

Patients with this lesion are predisposed to capillary leakage and fluid accumulation in their lungs. Excessive IV fluid flow rates can definitely cause this problem. Judicious use of hypertonic saline or hypertonic saline combined with Dextran 70 will help to facilitate intravascular volume expansion while avoiding pulmonary overload.

Head Trauma

Fluid therapy is aimed at maintaining cerebral perfusion pressure while decreasing intracranial pressure using mannitol at 1 g/kg IV over 15 minutes. Current recommendations for systemic resuscitation call for combined hypertonic saline and Dextran 70 given at 2 to 4 mL/kg over 5 to 10 minutes. In head trauma patients who are not hypotensive, you can give hypertonic saline at 4 mL/kg over 30 minutes.

PRACTICAL PEARLS FROM THE EMERGENCY ROOM

Michael Schaer, DVM, Dipl. ACVIM & ACVECC
College of Veterinary Medicine
University of Florida, Gainesville, FL

After 37 years of practice, a clinician can come to the clear conclusion that the practice of medicine consists of a fine blend of both the art and the science. Perhaps it might be rather bold to state that at times the value of the art might even surpass that of the science, even in the academic environment. The main objective of this collection of thoughts is to share some of the lessons that I have learned over the years with the hope that you will walk away with a few PEARLS that will benefit your sick patients. For the sake of simplicity, each pearl has been categorized according to organ system and will be presented in short and simple phrases. First, to share a bit of philosophy:

THE ART OF DIAGNOSIS

- To make the correct diagnosis, we need the right choices.
- To consider the right choices, we need the right information.
- To obtain the right information, we need to ask the right questions.
- Asking the right questions is the hallmark of clinical expertise.

—R. Kreisburg, MD

PATIENT EVALUATION

- Pallor can be caused by hypoxia, shock, anemia, and an epinephrine injection.
- Anemic pallor plus icterus causes a yellow hue.
- Pink mucous membranes plus icterus causes a more orange color.
- Massive generalized lymphadenopathy usually means lymphoma.
- If it looks, smells, and tastes (?) like pus, then it must be pus.
- Chest plus abdominal fluid accumulation commonly depicts a bad disease. Common causes: neoplasia, heart failure, diffuse inflammation, hypoproteinemia.
- Septic shock – Hypotension, hypothermia, thrombocytopenia.
- Skin turgor difficult to assess with cachexia and obesity.
- Sudden facial swelling, hemorrhagic oral mucosa, subdued mentation – Think Eastern diamondback rattlesnake envenomation (in Florida).
- Various causes of hyperventilation – Cardiorespiratory, pyrexia, brain disease, Cushing's, metabolic acidosis, anxiety, pain, shock, anemia.
- Fever plus immune-mediated disease – Appetite can persist.
- Fever plus sepsis – Anorexia.
- Nasal crustiness, scleral injection, muddy mucous membranes – Think uremia.
- On palpation: "Touch but don't squeeze the Charmin."
- Take the patient out of the cage and look at it!
- If something just "ain't" right – Think Neuro.
- Look under that tongue in any vomiting cat (and dog).
- Watch those rear legs for the earliest sign of weakness.
- THE BIG 6: PCV and TP, BUN, Glucose, UA, Chest/Abdominal radiographs.
- After therapeutic pericentesis, go back and repeat abdominal palpation so you don't pass the mass.
- Have you been palpating each mammary gland?
- A lump is a lump until you stick it.
- It's all in the history.
- Don't just look at it (a lump) – stick it!
- Heatstroke > 109.4°F – look out DIC.

UROGENITAL

- Rule out pyo in any sick intact female.
- Never let the sun set on a pyo (Garvey, M).
- Murky urine can be caused by: pus, chyle, crystals.
- Bilateral renomegaly means very serious disease: lymphoma, hydronephrosis, pyonephrosis, granuloma, inflammation, subcapsular edema, polycystic.
- Cats: 1 big kidney plus 1 small kidney can mean 1 fibrotic and 1 compensatory hypertrophic.
- Hematuria without stranguria – consider coagulopathy or renal bleed; however a...
- Recent renal bleed plus clots – can cause stranguria.
- Male dog plus stranguria – must radiograph to rule out obstructive uropathy.
- Cessation of polyuria in sick patient – consider oliguria/anuria – a bad sign.
- Oliguric renal failure – hyperkalemia common.
- High output chronic renal failure – normo- or hypokalemia common.
- Emphysematous cystitis – R/O diabetes mellitus.
- PD plus PU plus isosthenuria – consider chronic renal disease, even with normal BUN and creatinine, but watch out for Cushing's.
- Careful on "cysto" with pyometra, look before your stick!
- Prostate trends: carcinoma – asymmetrical, hard, mid or caudal pelvis; BPH – symmetrical, firm, anterior displacement.
- Empty urine line: anuria, recent emptying, obstruction.
- Always assess urine SG before starting fluid Rx.
- BPH: Passive penile bleed, normal urination, normal dog.
- Detection of urethral pathology in female dog, do rectal exam.
- Prostate inflammation → "prostatic shuffle".
- For oliguria, try dopamine at 3–5 μg/kg/min.

FLUIDS AND ELECTROLYTES

- SQ fluid administration – isotonic, 18- gauge needle, gravity flow
- Metabolic alkalosis plus hypokalemia common with upper GI obstructions.
- 0.9% NaCl plus KCl – Best for upper GI obstructions.
- TCO_2 >40 mEq/L is always metabolic alkalosis (usually with hypokalemia).
- TCO_2 < 10 mEq/L usually means severe metabolic acidosis.
- Potassium penicillin contains 1.7 mEq K+/million units – take heed when bolusing.
- Rx hypocalcemia when IV not an option: add 2.5 mL/kg 10% calcium gluconate to 150 mL 0.9% NaCl – give SQ Bid (for adult sized cat).
- When giving SQ fluids avoid hypokalemia – add 3.5 mEq/KCl/150 mL LRS – give SQ (for adult sized cat).
- All IV maintenance fluids should contain 7–10 mEq/KCl/250 mL; exceptions oliguria and untreated Addisonian.
- To make up 2.5% dextrose solution increments, add 12.5 mL D-50-W to 250 mL of fluids.
- Rehydrate before inducing diuresis; check urine SG first.
- Volume load with isotonic crystalloid.
- Intraosseous cannulas can be life saving.

GASTROINTESTINAL

- GI obstructions – Main sign is vomiting.
- Acute excruciating abdominal pain (like never before seen!) – Consider bowel infarction and intestinal volvulus.
- Causes of coffee ground vomitus – Gastric ulcers (primary/secondary), uremic gastritis.
- Melena causes – Upper GI lesion, thrombocytopenia.
- Occult blood loss – Think GI.
- Melena detection – "Let your finger do the walking".
- Black stools – Upper GI bleed, thrombocytopenia, swallowing blood, "Pepto," iron, charcoal.
- Elevated BUN plus normal creatinine – Consider upper GI bleed, especially if kidney can concentrate urine.
- Bile in vomitus signifies pyloric patency.
- The lower the obstruction, the more feculent the vomitus.
- Sudden mental depression 2–3 days post enterotomy – rule out dehiscence and sepsis.
- Never let the sun set on a linear foreign body intestinal obstruction.
- Diffuse inflammatory bowel disease can often be diagnosed with distal colon biopsy.
- Sepsis can cause cholangiostasis.
- Gas in the gallbladder is a bad and a surgical disease.
- Bilirubinuria without hemolysis in cats signifies liver disease.
- J-tube feeding for managing the prolonged period of NPO in pancreatitis can be beneficial.
- Look for pancreatic pathology when the right kidney is easily visible on a radiograph.

CARDIORESPIRATORY

- Many die without ever showing open mouth breathing.
- Watch for the exaggerated abdominal component.
- Cardiomegaly does not always cause tall EKG complexes.
- A standing lead 2 EKG is satisfactory for rate, rhythm, and interval measurements.
- Do not use beta blockers until pulmonary edema resolves.
- Muffled chest sounds: fluid, mass, air, obesity, deep chested, "plugged ears."
- Diffuse muffling – Usually chest fluid.
- Dorsal muffling – Air or mass in chest.
- Coughing cats – Allergic bronchitis, flukes, lung worms, heartworms, hair or foreign body in trachea, tumor.
- Sudden onset diffuse pulmonary infiltrates, think ARDS.
- Cats with heart disease rarely cough.
- Bacterial pneumonia plus leukopenia (bone marrow associated) – causes minimal radiographic infiltrates.
- Heartworm treated dog at discharge: dispense prednisone and furosemide for the earliest signs of PTE.
- Echocardiogram for diagnosing vegetative endocarditis.
- 3–5 mg (total) ketamine IV for a dyspneic cat can allow "survival" radiographs.
- Remember – Good side UP when radiographing dyspneic patient.
- Digoxin intoxication can cause any cardiac arrhythmia.
- Aspiration pneumonia can be worse when H_2- or H^+ blockers are used due to altered GI microflora.

NEOPLASIA

- Cutaneous mast cell tumors can mimic any type of skin growth.
- Assume any firm mammary nodule as carcinoma until proven otherwise.
- Mammary tumors – Don't stick it – cut it.
- Don't miss lymphangitic inflammatory mammary carcinoma.
- Nasal disease can do anything.
- Copious mucoid nasal discharge – Think nasal adenoCA.
- Try gastric biopsy forceps for nasal biopsy.
- Closed mouth nasal cavity radiographs are useless.
- Cancer can cause elevated T. WBC and fever.

DRUGS

- Observe for drug interactions.

- Do not use theophylline with Cipro – causes theophylline OD.
- Best avoid IV route for thiamine (better IM) and Vitamin K1 (better SQ).
- Rehydrate prior to using aminoglycosides.
- Prednisone for craniomandibular osteopathy.
- Cimetidine enhances metronidazole-induced neurotoxicity.
- Aspiration pneumonia worse when H_2-blockers in use.
- Panmycin can cause fever in cats.
- Follow all oral doxycycline with water to swallow.

HEMATOLOGY

- Unclotted blood in clot tube – Consider coagulopathy.
- Massive splenomegaly – Splenic torsion, lymphoma, myeloproliferative or mast cell splenic neoplastic infiltrate.
- Thrombocytopenia plus anemia – Causes pale petechia!
- Fleas plus thrombocytopenia – Cause "lots of" lumbosacral petechia.
- Low WBCs, low RBCs, low platelets – Rule out bone marrow suppression.
- Fulminant hemolysis – Anemia, Hb-emia, Hb-uria, weakness, depression, +/- vomiting.
- Bone marrow-derived leukopenic animals don't make pus!
- Keep IMHA and ITP patients on long-term q2d maintenance prednisone for 9–12 months.
- Try Danazol (Danocrine) with prednisone for refractory IMHA and ITP.
- Observe for autoagglutination and spherocytes in IMHA.
- Newly acquired bleeding, think warfarin intoxication.
- A normal bleeding time ensures adequate platelet hemostasis, a normal platelet count does not.

ENDOCRINE

- Hypercholesterolemia plus elevated CK – Rule out hypothyroidism.
- U-100 syringe (or TB) must be used for U-100 insulin.
- Do not forget K+ when treating DKA.
- Oliguric diabetics have marked hyper-glycemia.
- Glycosuria can occur with diabetes, proximal renal tubular disease, stress, IV dextrose.
- Marked hyperglycemia with minimal glycosuria - consider oliguria/anuria.
- Morning marked glycosuria and afternoon diminished glycosuria – Typifies transient insulin response (need split dose).
- Can use soiled litter to detect glycosuria.
- Hyperglycemia can sometimes be detected in tears.
- The "Accucheck" blood glucose meter is nice (and inexpensive).
- Assess the eclampsia dog for hypoglycemia.
- Try mannitol or hypertonic saline for severe hypoglycemic encephalopathy.
- When Florinef does not work well, use DOCP and prednisone.
- The hypocalcemic cat has not read the book.
- Keep an eye out for the atypical Addisonian.

NEUROLOGY

- Rapid onset LMN paralysis, think – Ticks, organophosphate, botulism, polyradiculoneuropathy, metronidazole, coral snake.
- Cats with dilated pupils and blank stare – Think thiamine.
- Coma – Diffuse cerebral, stem, but don't forget metabolic.

INTOXICATION

- Ethylene glycol fluoresces.
- DMSA (dimercaptosuccinic acid - Succimer; McNeil) – An oral Rx for lead poisoning.
- Unexplainable radiodense particles in the bowel - think lead.
- 4-methylpyrazole 5% for antifreeze intoxication; avoids hangovers.
- Newer anticoagulant rodenticides – Treat for 4–6 weeks.
- Newly acquired bleeding – Think warfarin OD.

PATIENT MANAGEMENT

- Old dogs are poorly tolerant to tranquilization.
- Avoid sedating acutely ill patients unless absolutely necessary.
- Don't sedate at the end of day.
- Increased spontaneity might pre-empt death.
- Heparinized syringe might contain as much as 200 units heparin – too much for puppies and kittens.
- Traumatic ear flush can cause inner ear and vestibular disease.
- Cats hate atropine drops (use ointment instead).
- Some pathologic bladders can leak after cystocentesis.
- Do not forget THIAMINE in cats.
- Glycerine suppositories for patients with pelvic fractures will be most appreciated!
- Three (3) mg (total dose) ketamine IV – Can adequately restrain the sick cat with urethral obstruction.
- Careful with SQ fluids – dogs are not cats and they like to slough!
- Manual expression of a male dog's bladder is hazardous to its health – It can rupture.
- SQ fluid administration – Stay behind the scapula and in front of the wing of the ilium. Use 18-gauge needle and 50 mL/site (adult cat).
- Don't forget glucose for the babies.
- Imipenem for life threatening infections.
- A clean cat is a happy cat.
- No Fleet enemas for obstipation, unless you want to treat a good case of hypocalcemia.

- When is the last time you hugged your patients?
- A dynamic duo: Good science and experience.
- Heat lamp and rubbing alcohol = one HOT dog.
- Nothing is routine.
- If client can not afford a "Cadillac," there is nothing wrong with a "Chevy."
- Body bandage in cats cause pseudoparalysis.
- Rapid abdominocentesis is effective and safe for chronic ascites, except when it is caused by chronic liver disease whereby simultaneous IV plasma or albumin infusion is recommended.
- Best avoid IV B_1 and K_1 – Give SQ or IM.
- Never kill 'em based on cytology results.

CARING FOR THE CRITICALY ILL ICTERIC CAT

Michael Schaer, DVM, Dipl. ACVIM & ACVECC
College of Veterinary Medicine
University of Florida, Gainesville, FL

The detection of icterus in the dog and cat poses a diagnostic challenge to the veterinary practitioner. Because icterus has several very different etiologies, it is best to pursue the cause initially by attempting to answer the question: Is the icterus due to a prehepatic, hepatic, or posthepatic disorder?

PREHEPATIC

This particular cause of icterus accompanies a hemolytic condition that allows for the accumulation of unconjugated bilirubin. Some of the causes of hemolysis in the cat are hemobartonellosis (*Mycoplasma haemofelis*), adverse drug reactions (acetaminophen, methylene blue), autoimmune hemolytic anemia (often FeLV positive), transfusion reactions, and hemolytic disease of the newborn. The history and the physical examination findings will often help to differentiate the causes of prehepatic icterus.

The laboratory findings will support the prehepatic origin of icterus based on the presence of a regenerative anemia and other features depending on the particular etiology as shown with RBC Heinz body formation with certain drug toxicities such as acetaminophen and methylene blue. Hemobartonella (Mycoplasma) should be searched for. In the cat, it should be noted that many of the positive cases of *Mycoplasma haemofelis* or the Coombs positive hemolytic anemia are also FeLV positive. Hemoglobinuria and hemoglobinemia usually accompany an intravascular hemolysis.

Treatment depends on the particular etiology. Acceptable cross-matched blood should be given if the patient is weak and depressed or if it has a packed cell volume of < 15%. Discontinuing any causative offending drug should be immediate if the hemolysis is drug related. In the case of IMHA, immunosuppressive doses of glucocorticoid (prednisone 1–2 mg/kg once or twice daily) are begun immediately. Other immunosuppressive or immune modifying drugs can be given depending on the patient's status and its initial response to treatment. Persistently FeLV positive cats usually have a very guarded to grave prognosis.

HEPATIC

This includes both primary and secondary causes of hepatic disease. Only the primary and more common types will be discussed here.

Feline Primary Idiopathic Hepatic Lipidosis

This is a common syndrome in the indoor cat. The history often provides a stressful event that triggered the inappetence. Anorexia and its effects on protein and lipid metabolism may play an important pathogenetic role. Abnormal triglyceride metabolism is thought to reflect other derangements in hepatocyte functions that contribute to hepatic failure.

There is no age, breed or sex predisposition, but obesity is considered a contributing factor. The common clinical features include anorexia of several days to weeks duration, lethargy, and depression. Intermittent vomiting and diarrhea can also occur. The physical examination often detects a palpably enlarged smooth surfaced liver, icterus, varying degrees of dehydration, and evidence of weight loss.

The clinical pathologic abnormalities include a nonregenerative anemia and elevated serum transaminase, alkaline phosphatase, and bilirubin levels. Bilirubinuria is common and indicative of liver disease in the cat in the absence of hemolysis. Coagulation abnormalities occur with the advanced form of disease. The presence of hepatic fat deposits found on cytology specimens obtained by fine needle aspiration or histopathologically on a liver biopsy specimen are confirmative.

Treatment for idiopathic hepatic lipidosis entails restoring hydration along with the provision of nutritionally balanced feedings. The latter can be accomplished with "finger feeding" baby food (without onion powder) or more efficiently through nasogastric, pharyngostomy, or gastrostomy tubes. Tube feeding will allow for the delivery of a more nutritionally balanced diet.

Ursodeoxycholic acid (Ursodiol) is a choleretic agent that increases bile flow and decreases bile toxicity. It is dosed at 10–15 mg/kg once daily orally.

S-Adenosylmethionine (SAMe) is a product that increases hepatic glutathione levels thereby providing a protective antioxidant effort for the liver. The dose is 18 mg/kg once daily orally.

Milk thistle also has protective effects on the liver. The compound containing silymarin extract is dosed at 0.25 mL q8–12h orally.

B vitamins are generally administered. This author prefers not to use benzodiazepine tranquilizers to stimulate the appetite because of sedative side effects and their potential for hepatotoxicity in the cat.

The prognosis is fair to guarded depending on whether or not the anorexia disappears and the appetite returns. Predisposing psychological stressors might be difficult to reverse.

Hepatic lipidosis in the dog is generally a secondary disease associated with diabetic ketoacidosis. It will resolve once the primary disorder is cured.

Cholangiohepatitis

This is an inflammatory disorder of the hepatobiliary tree. In the cat it has two main types: 1) suppurative cholangitis/cholangiohepatitis and 2) nonsuppurative cholangiohepatitis. Advanced inflammatory disease can progress to cirrhosis. These syndromes can be associated with other conditions such as duodenitis, pancreatitis, and cholecystitis. In the tropics, cholangiohepatitis can be caused by the liver fluke, *Platynosum concinnum*. Cholangiohepatitis in the cat can occur with cholecystitis with the latter often becoming a surgical disorder when it becomes emphysematous or if it is associated with biliary outflow obstruction.

The clinical signs include varying degrees of anorexia, weight loss, dehydration, vomiting, diarrhea, hepatomegaly, and jaundice. Fever is sometimes present especially in the cat with suppurative cholangiohepatitis. Anterior right-sided abdominal discomfort might be evident on palpation. The clinical pathologic features include elevated serum transaminases, alkaline phosphatase, and bilirubin levels and bilirubinuria. A neutrophilia is common with the suppurative type. Eosinophilia is occasionally present with fluke infections in the cat. A liver biopsy is necessary for a definitive diagnosis. Some advocate ultrasound guided percutaneous gall bladder aspiration for culture and cytology, but this procedure might cause leakage and bile peritonitis.

Fluid therapy and B vitamins are important for both types of cholangiohepatitis. Vitamin K_1 should be given when there is obstruction to bile flow. Antibiotics are strongly recommended for the suppurative form; those commonly used include those effective against gram negative bacteria. SAMe and milk thistle are also used as liver support drugs.

For nonsuppurative cholangiohepatitis in the cat, prednisone is recommended at a daily dose 2.2 mg/kg for 1 to 2 weeks and then slowly tapered to an alternate day regimen over a 4- to 6-week period.

Feline liver flukes are treated with praziquantel at 20 mg/kg once daily for 3 consecutive days. Fenbendazole at 50 mg/kg PO can also be given for 5 consecutive days. The prognosis is fair to good if the condition is treated before biliary fibrosis becomes established.

Cholestasis

Cholestatic hepatopathy is characterized by bile stasis within the canaliculi. It can occur with cholangitis, cholangiohepatitis, or it can be due to adverse drug reactions on the liver. Other causes include various enterotoxins, sepsis, and certain inflammatory disorders such as acute pancreatitis. These conditions are managed medically along with the discontinuation of any predisposing medications, herbs, or other hepatotoxins and the treatment of the primary underlying disorder. Liver supportive measures can include the administration of ursodiol, SAMe, milk thistle, and adequate nutrition and vitamins.

POSTHEPATIC

The posthepatic causes of jaundice in the cat include those disorders that cause common bile duct obstruction.

The clinical pathological features of this group of disorders include remarkably elevated serum alkaline phosphatase, cholesterol, and bilirubin levels. Serum transaminase levels will vary from mild to moderately elevated. The hemogram is seldom contributory, except for prolonged coagulation times due to the inactive vitamin K dependent factors II, VII, IX, and X. Parenteral vitamin K_1 treatment is recommended.

Radiographs and abdominal ultrasound examinations might suggest masses or markedly dilated bile ducts. Surgical exploratory is essential for an absolute diagnosis and the determination of the treatment plan and prognosis.

CRITICAL CARE FOR THE CAT IN LIVER FAILURE

The main concerns in treating the cat with severe liver disease are nutrition, fluid and electrolyte balance, hepatic encephalopathy, and coagulation disorders.

Nutrition

Oral feeding or feeding with the assistance of a pharyngostomy, esophagostomy or gastrostomy tube would be the ideal way to maintain the patient so long as it is not vomiting. In the case of significant vomiting (more than twice/day), parenteral nutrition will have to be instituted. It is essential to provide an adequate caloric base to allow the cat to be maintained in an anabolic state. The required amount of calories needed per day (RER) can be computed using the formula where

$$\text{RER} = 70 \times (\text{Body weight in kg})^{0.75} \text{ or}$$
$$\text{RER} = 30 \times (\text{Body weight in kg}) + 70$$

This formula has to be adjusted for catabolism, dietary thermogenesis, and the presence of sepsis. The diet should contain good quality protein and must not be restricted unless hepatic encephalopathy, hyperammonemia, or ammonium biurate crystalluria are present. In the absence of vomiting the protein requirement can be met with most available prescription diets that contain high quality protein, adequate fat and carbohydrate along with adequate vitamins and minerals to meet the cat's daily requirements. If the cat is being tube fed the use of a blender will greatly facilitate its administration. Cats on enteral nutrition will be fed commercially available liquid diets that are made of the right consistency for enteral tube administration. It is important to start such diets slowly so that osmotic diarrhea is avoided.

Sodium intake should be limited to 100 mg/100 kcal energy requirement in hypoalbuminemic cats and in those with ascites. The palatability from such a diet will probably suffer, and in the cat that is already anorectic, tube feeding will probably be essential.

The critically ill cat can very likely become depleted of thiamine and vitamin B_{12}. Thiamine deficiency can cause a severe polioencephalomalacia and is best avoided by providing normal daily needs. Thiamine hydrochloride injection (50–100 mg IM or SQ) should be given in any cat that is showing signs compatible with thiamine deficiency (starry-eyed gaze, fixed mid-position or dilated pupils, ataxia, dementia, and dysequilibrium. Fifty milligrams can be given daily for the next few days followed by normal dietary amounts. Vitamin B_{12} (cobalamine) supplementation might help cats with co-existing pancreatic and small intestinal disease. Blood cobalamine levels can be sent to a commercial laboratory and treatment can be provided with 0.5–1.0 mg of B_{12} IM or SQ every 7 to 21 days.

Vitamin E and Vitamin K_1 are also important nutrients that should be provided for their activity against cellular oxidative injury and coagulation disorders, respectively. A recommended dose for Vitamin E is 10 units/kg/day. Vitamin K_1 is necessary for the facilitation of Factors II, VII, IX and X and is dosed at 0.5 to 1.5 mg/kg sid-bid. **It is important to remember that no vitamin injection should be given by IV push because it will likely cause an anaphylactoid reaction.**

Fluid Therapy

Fluid therapy and meticulous protocols for its administration is an essential part of caring of critical care medicine. Cats are very susceptible to having intravenous fluid overload and should therefore be monitored closely. The special considerations concerning fluid therapy for cats with liver disease include hypovolemia, hypoalbuminemia, blood loss, predisposition to edema and body cavity effusions, and sepsis caused by breaks in sterile procedure. The tendency for sensitivity to fluid overload is because the patient with chronic liver disease can have an active renin-angiotensin-aldosterone system because of the ineffective blood volume they might have. One good way to administer parenteral fluids to such patients is to infuse a slow infusion of both crystalloids and colloids. This can be done with alternating or combined delivery methods. The increased plasma oncotic pressure delivered with this fluid formulation will help restore intravascular Starling's forces to normal by expanding intracellular volume, limiting the requirement of crystalloid, and allowing for a more prolonged lasting effect of the volume expansion efforts. It is recommended that only one third of the normal amount of crystalloid be given if a colloid is given at a dose of 10 mL/kg which is the 24-hour recommendation of Hetastarch for the cat. If either Hetastarch or Dextran 70 is used, it is important to consider their effect on the patient's coagulation status because of their known tendency to antagonize blood clotting which is already a concern in a cat whose liver disease is already compromising hemostasis.

Albumin infusions will benefit the patient with hypoproteinemia and when combined with rapid paracentesis on the ascitic cat, the procedure might avoid being complicated by life-threatening hypovolemia. Although human albumin has been given to several dogs without allergic complications, it might be safer to use plasma from another cat until more is known about the cat's ability to tolerate plasma proteins from other animal species. Any foreign protein carries the threat of anaphylaxis with it thereby calling for much diligence during its administration. All allergic reactions must be met with immediate discontinuation of the plasma or albumin infusion. If necessary, parenteral epinephrine must be given at a dosage of 0.01 mg/kg IM and repeated in 20 minutes if anaphylaxis occurs.

Dextrose-containing solutions should be used whenever the blood glucose concentration cannot be maintained within normal limits of 70 to 125 mg/dL. Hyperglycemia can cause several complications including immune compromise thus predisposing to infection, osmotic diuresis with its attending loss of important electrolytes and water soluble vitamins, and a contributing factor to the formation of respiratory acidosis. However if hypoglycemia is present it should be countered with dextrose administration. Hypoglycemic encephalopathy should be treated immediately with dextrose injection at a dose of 0.5 g/kg, which is met with 1.0 ml of 50% dextrose IV or 2 mL/kg 25% dextrose solutions. Intravenous injections of such hypertonic solutions must not be allowed to extravasate because of the extensive tissue sloughing that can occur.

Treating Anemia

The anemia that occurs with liver disease can be uni- or multifactorial. Blood loss can occur from slow bleeding gastric ulcers, especially if mast cell cancer is the cause of the liver disease. Liver disease alone has been associated with gastric ulcers. Other causes can be the anemia of chronic disease or that due to any co-existing disease such as feline leukemia virus. Lastly and by no means least, iatrogenic blood loss will occur from too frequent phlebotomies. When anemia is expected, a donor should be identified, cross-matched, and be readily available when needed. The anemia of chronic disease might even benefit from Epogen treatment, but here again judicious use is important in order to avoid autoimmune destruction of the cat's red blood cells.

Hepatic Encephalopathy

This is a critical part of treating any cat with severe liver disease. The major strategies include avoiding the onset of hypokalemia or metabolic alkalosis; treating GI bleeding vigorously and expediently; maintaining normal blood pressure; avoid protein administration; and maintain normal fluid, pH and serum electrolyte balance.

Adjusting enteric bacterial flora is sometimes necessary and this can be brought about by several different methods. Neomycin or metronidazole can be given orally in order to remove the bacteria that are producing ammonia within the intestinal lumen. Retention enemas containing neomycin and saline in a proportion of 7:1 can also be used if the cat is comatose or where oral medication is otherwise restricted as occurs with severe vomiting. Lactulose solution can also be used to adjust the bacterial flora through its ability to maintain an acidic environment within the lumen of the colon thereby preventing the conversion of ammonium to the more absorbable ammonia.

General Patient Care

Any care delivered to cats should always include measures that consider their species requirements for gentle handling, minimal restraint, and measures taken to keep them as clean as possible. Baths should be given to remove any soiling from feces or urine. All catheters should be inspected for potential sites of contamination or underlying skin inflammation and any such occurrences should be managed as soon and as appropriately as possible. Any medications that are not necessary should be omitted and care should be taken to avoid drug interactions. Intravenous catheter sites should be ideally rotated every 3 to 4 days, but because of the logistical difficulties encountered with the cat being such a small species, many intravenous catheters can be retained for as long as 7 days without consequence, but under such conditions extremely meticulous catheter care is essential.

BILE PERITONITIS — WHITE BILE

Rick L. Cowell, DVM, MS, MRCVS, Diplomate ACVP
IDEXX Laboratories Inc
Stillwater, OK

Effusions due to the release of bile into the abdominal cavity resulting in bile peritonitis are often in the exudate category. The effusion is typically greenish to yellow-orange and this color to the effusion often causes one to consider bile peritonitis. The nucleated cells in the effusion are composed of variable numbers of neutrophils, macrophages, mesothelial cells, and lymphocytes. Cytologically, phagocytized bile pigment appears blue-green to yellow and often can be seen within macrophages and/or extracellularly. Diffuse bile peritonitis is readily suspected clinically by the color of the fluid and cytologic findings. Bilirubin levels should be measured in the serum and abdominal fluid and diagnosis is confirmed by documenting abdominal fluid bilirubin levels greater than twice the serum bilirubin levels.

Occasionally bile peritonitis occurs where minimal or no bile pigment is visible on cytologic evaluation of the abdominal fluid and the primary finding is a basophilic, amorphous, extracellular, mucinous material that appears fibrillar. The mucinous material is acellular but inflammatory cells from the effusion are often caught up in the material. Abdominal fluid bilirubin concentration is often many times greater than the serum bilirubin level. The clear biliary fluid is thought to originate from the common bile duct epithelium. Extrahepatic biliary obstruction is thought to lead to biliary stasis and the biliary epithelium produces a clear, bile free mucoid material. A tear in the extrahepatic biliary tree or a ruptured gallbladder releases this material into the abdominal cavity resulting in bile peritonitis with "white bile."

THE COMPLETE URINALYSIS

Rick L. Cowell, DVM, MS, MRCVS, Diplomate ACVP
IDEXX Laboratories
Stillwater, OK

Dennis B. DeNicola, DVM, PhD, Diplomate ACVP
IDEXX Laboratories
Westbrook, ME

Complete urinalysis should be performed every time a need to evaluate the renal system exists. Routine urinalysis can easily and accurately be performed in a veterinary practice. There are different components of a complete urinalysis; the physical examination (gross inspection of the urine), the chemical examination ("dip stick" test), and the microscopic examination. These should be performed soon after the collection of the urine specimen.

URINALYSIS – PHYSICAL EXAMANATION

The gross inspection of a urine specimen can provide significant information regarding any identifiable disease process involving the urinary system. Some of the more common or useful physical features of urine specimens are outlined briefly below.

Color

Color of the urine can provide potential insight into the various formed elements of the urine. Red urine is seen with either hemoglobinuria or intact erythrocytes. With intact erythrocytes, the supernatant of the urine should be clear following centrifugation where erythrocytes are forced into a pellet in the centrifuge tube. Brown-red colored urine may be seen associated with myoglobinuria or oxidized hemoglobinuria. Dark yellow colored urine may be seen associated with marked bilirubinuria.

Turbidity

Turbidity of any type of a fluid specimen is related to particular matter in that specimen. With turbid urine specimens, the particles that more commonly give the urine a turbid appearance include bacteria, inflammatory cells, erythrocytes, and crystals.

Odor

A strong ammonia odor to a urine specimen may suggest breakdown of urea, which should be in relatively high concentrations in a normal urine specimen, into ammonia by urea splitting bacteria. This simple physical feature of a urine specimen may provide immediate information regarding underlying bacterial infection of the urinary tract.

Specific Gravity

Specific gravity is commonly estimated from the refractive index of a urine specimen with the use of a refractometer. The specific gravity is predicated upon the presence of a concentration of small solutes. It is used as a simple measure of the ability of the kidney to concentrate or dilute a urine specimen and in conjunction with the measurement of serum urea nitrogen or creatinine, proves essential in the classification/identification of "renal failure". Selected solutes in high concentration (eg, glucose and protein) that normally should not be present in typical urine specimens may contribute slightly to the specific gravity/refractive index of the urine.

URINALYSIS – CHEMICAL EXAMANATION

Almost anything that can be measured in the serum or plasma of an animal with routine laboratory clinical chemistry methodologies can be measured in urine specimens. The most commonly performed chemical test in veterinary medicine is the simple dry chemistry reagent strip (dipstick). If one follows the instructions carefully, the volume of urine collecting on each of the reagent pad is very precise and the results obtained are relatively accurate. It is critical for some of the tests to read the color change result precisely at the time suggested by the manufacturer for that particular test. If the reagent strips were maintained in a desiccant at room temperature as is suggested by the manufacturer and if the dipping process is followed correctly, as the manufacturer suggests, the results are extremely valid. The primary problem that most people will encounter is when they are working with a urine specimen that is darkly colored red or brown-red. This coloration of the urine often interferes with accurate characterization of the color change taking place on the reagent strip. In this case, one must rely on backup chemical testing procedures that are more labor intensive and more expensive than the reagent strip. These specialized chemical tests are not routinely performed in a veterinary practice but can be performed in most reference laboratory facilities. Some of the more common dry chemistry reagent strip tests are listed below with abbreviated comments on interpretation. Detailed information is typically provided with the individual strip information inserts to include comments regarding interfering substances and overall interpretation; review of this information is recommended.

pH

Multiple factors influence the pH of a urine specimen. Some of these include rate of renal excretion of hydrogen ions (H^+), renal resorption of bicarbonate (HCO_3^-), sample age, and the presence of urea splitting bacteria causing an increase in pH. Knowledge of the urine pH may give some insight into the overall metabolic acid–base status of an animal if electrolyte distributions in the plasma are not seriously abnormal. Knowledge of the urine pH may also be helpful in interpreting other components of the urine. For example, severely alkalotic urine samples with a pH > 8.0 may have significant disintegration of RBCs, WBCs and casts, which will make it difficult to identify these abnormal formed elements in a urine specimen. Crystal identification may be aided with the knowledge of the pH also.

Protein

Protein determination in a urine specimen can be accomplished by different methods. The dipstick pad for protein is extremely sensitive for albumin but relatively insensitive to globulins and for some globulins such as Bence-Jones proteins (light chains of immunoglobulins) the pads are almost completely insensitive. The test pad is dependent upon reaction of the amino groups of proteins to react with the color of the acid–base indicators in the pads. False positives are reported for significantly alkaline urine samples. Certain types of detergents (quaternary ammonium compounds) may cause false positive reactions also. Interpretation of the dipstick protein pad must be made in light of other information about the urine (eg, inflammation and hematuria). The dipstick protein pad is used as a preliminary screen for proteinuria related to renal causes (glomerular or tubular). If the urine is not concentrated, a 1+ protein result is considered significant; however, if the urine is concentrated, a 2+ protein result is required before any significance is suggested. Sulfosalicylic acid (SSA) precipitation test is commonly used in most reference laboratories to confirm proteinuria suggested by the dipstick result. However, both tests should be considered screening (semi-quantitative) tests. True chemical determinations can be performed for more accurate protein quantitation and determination of the urine protein: urine creatinine ratio can help in assessing the degree of proteinuria present.

Glucose

Because of the ability of the proximal renal tubules for resorption of any plasma glucose that might make it through the glomerular filtrate, glucose concentrations in urine of clinically normal animals are extremely low and below the level of sensitivity for detection by the dipstick dry pad for glucose. True persistent glucosuria is associated with persistent or prolonged hyperglycemia in most cases; some cases of tubular dysfunction (Fanconi syndrome) may result in glycosuria without persistent hyperglycemia. False-positive reactions with the dipstick pad for glucose may happen with exposure to formaldehyde, the use of outdated pads or the presence of hydrogen peroxide. False-negative reactions can occur with high concentrations of ascorbic acid (inhibits the reaction pad) or some selected drugs like salicylates or tetracyclines.

Ketones

The ketone dipstick pad primarily measures the presence of acetoacetic acid and acetone; beta-hydroxybutyrate is not detected. The presence of measurable ketones in the urine indicates abnormalities in metabolism of fat (starvation or malnutrition, unregulated diabetes mellitus, sheep pregnancy toxemia, bovine ketosis, etc.). More sensitive qualitative tests for ketones are available if there is a questionable result.

Bilirubin

Accurate measurement of the bilirubin pad on the dipstick is often difficult because the degree of color change is relatively subtle and the yellow discoloration of the urine sample with bilirubin interferes with accurate detection of these subtle changes. Interpretation is different with different species. The dog has a low renal threshold for bilirubin; therefore, bilirubin is present and identified as a trace to 1+ result in most canine urine samples. Significantly concentrated canine urine samples have 2+ bilirubinuria as well as the presence of bilirubin crystals in the urine even when there is no hyperbilirubinemia. The cat on the other hand has a high threshold for bilirubin and essentially any detection of bilirubin in the urine of cats is significant. Significant bilirubinuria is used to support cholestasis or hemolytic disease. False-negative bilirubin results are possible with old urine samples because of degradation (hydrolysis) of conjugated bilirubin or because of conversion of bilirubin to biliverdin when exposed to UV light. Also, high concentrations of vitamin C can inhibit the reaction pad giving a false-negative result. Backup qualitative tests for bilirubin are available if there is any question in the result from the dipstick.

URINALYSIS – MICROSCOPIC EXAMANATION

Microscopic examination of urine sediments requires the availability of a good quality microscope. If one is not available accurate assessment of the formed elements of the urine will not be possible. Both a good 10x and 40x objective is required on the microscope. When examining the urine sediment microscopically, most people use a bright field microscope that is used for routine hematology and cytology specimens. When examining the urine specimen, putting the light out of bright field microscopy settings by lowering the substage condenser and partially closing the iris on the microscope may prove helpful in making various formed elements easier to visualize. The preparation of the sediment requires only a simple tabletop centrifuge with a relatively slow speed to allow sedimentation of the formed elements without mechanical damage to these elements. Most people examine the sediment on unstained preparations, but there are a series of commonly used stains including some developed specifically for urine sediment examination (Sedi Stain) or routine Romanovsky stains commonly used in hematology or cytology specimen analysis (Diff Quik, Wright's stain, etc.). The initial examination of an unstained specimen will be difficult. However, learning how to read these specimens precludes the observation of stain precipitate and misidentifying this as an organism or crystal and prevents the bacterial or fungal contamination of the stains with subsequent overgrowth and misinterpretation of the presence of these organisms. Practice with some pseudo urine specimens by using a clean urine specimen spiked with various "formed elements" commonly seen in urine sediment specimens. Epithelial cells from the buccal mucosa (spatula gentle scraping of the oral cavity), leukocytes and erythrocytes from anticoagulated whole blood originally submitted for hematology evaluation, and potential neoplastic or various inflammatory cell populations from other specimens (fine needle aspirates of solid masses, sediment smears of effusions, etc.). Some of the more commonly encountered formed elements in urine are briefly discussed below.

CELLS

Erythrocytes

Red blood cells in the urine, hematuria, can originate from any region of the urinary tract but most commonly is associated with local bleeding in the urinary bladder associated with cystitis or it is iatrogenic during the collection process. In fresh urine, close examination reveals their biconcave shape. In dilute urine, erythrocytes swell and lyse resulting in hemoglobinuria rather than hematuria. In concentrated urine, erythrocytes typically crenate and resemble crenated erythrocytes in the peripheral blood with multiple short uniform sharp cytoplasmic projections. Practice in the identification of these cells in urine is relatively simple. Place a drop of EDTA anticoagulated blood into dilute, non-concentrated and concentrated urine samples and see the effect on the erythrocytes.

Leukocytes

White blood cells are commonly seen with cystitis or any other type of inflammatory disease in the urinary tract. Typically only very few leukocytes are seen in normal urine (less than 2 WBC/HPF). These cells are usually spherical and in contrast to the erythrocytes, nuclei are visualized with careful inspection at 40x objective magnification field of view. Neutrophils are the most common leukocyte seen in urine and the lobed nucleus is usually very easy to identify even in unstained preparations. Mononuclear leukocytes, monocytes, macrophages and lymphocytes, have rounded to slightly indented nuclei. If there is ever a question regarding the identification of leukocytes or recognizing what type of leukocyte is present, preparation of an air-dried smear of the urine sediment and staining with a stain you use for hematology is recommended. This will allow direct detailed visualization of nuclear and cytoplasmic morphology similar to evaluation of a blood film.

Epithelial Cells

Differentiation between renal tubular, transitional and squamous epithelial cells from different regions of the urinary tract may take some practice. These cells are generally larger than the leukocytes and they typically have more cytoplasm (lower nuclear/cytoplasmic ratios) than leukocytes. Squamous epithelial cells are commonly larger than transitional epithelial cells (two to four times larger than leukocytes) and renal tubular epithelial cells are generally only slightly larger than leukocytes. Transitional epithelial cells may take on a polygonal or irregular shape with variably prominent projections from the cytoplasm. Close inspection even in an unstained preparation should allow visualization of the relatively centrally located round to oval nucleus commonly seen in these epithelial cells. They may be present individually or in small cohesive clusters. Collection of relatively large numbers of transitional epithelial cells with catheterized specimens is common due to the mechanical sloughing during the placement of the catheter.

CRYSTALS

Most crystals found commonly in the urine of animals are not clinically significant. Fresh, unrefrigerated urine samples generally do not have crystals or have only very few. If a urine sample is allowed to stand for any period of time, crystals will form if the correct compounds are present, particularly in a supersaturated specimen. Most crystals have typical morphologic appearances that allow identification. Knowledge of the dependency of pH on the formation of crystals may prove helpful also. Certain crystals will form only under certain pH situations.

CASTS

Casts are formed in the tubules of the kidney as a result of clumping of cells or other material within a protein matrix. These formed elements of the urine sediment prove to be helpful indicators of renal disease. Except for protein casts, renal tubular casts indicate tubular damage. Accurate identification of the various casts may be difficult because there is actually a transition between the different types of casts. In addition, they may have different formed elements including cells, granular proteinaceous cellular debris, protein, and fat. Casts are identified by several common features. These cylindrical structures have parallel sides and typically one end of the cast is irregularly ragged and the other end is potentially smooth and blunted. The ragged end represents the end of the cast that has broken off any remaining cast material within the renal tubules. The smooth end represents the end of the renal tubular thrombus, which represents the cast that eventually is sloughed and potentially identified in the urine sediment.

MISCELLANEOUS COMPONENTS OF THE URINE SEDIMENT

A variety of components may be found in the urine of normal and abnormal animals. Bacteria identified as uniform small round (coccal) to short rod-shaped structures that elicit “Brownian motion” because of their small sample size. If there is ever a question related to the accurate identification of bacteria, air-dried sediment of the urine stained with the stain commonly used in hematology can be helpful in characterizing these small particles. Yeasts and other structures including contaminating fungal forms from the environment may be found in urine also. Sperm may be seen and are typically easy to recognize based upon the distinctive structure and the fact that many will be viable and motile in a fresh urine specimen. Structures such as filter / fiber fragments and mucus strands may prove interfering with the accurate identification of casts. Glove powder must not be confused with crystals that are truly formed in the urine.

CYTOLOGY OF INFLAMMATION

INFLAMMATORY CYTOLOGY

If the reaction is strictly inflammatory, then the left side of the flow chart shown in Figure 1 in the companion article, General Approach to Cytologic Interpretation, in this proceedings is followed. The inflammation must first be classified as neutrophilic/eosinophilic, mixed, or macrophagic. Classification is done arbitrarily and is based solely upon the relative proportions of the various inflammatory cells in the reaction. If neutrophils (or eosinophils) predominate (greater than 80% of the inflammatory cells present), the reaction is classified as neutrophilic (suppurative or eosinophilic). If neutrophils and mononuclear cells are present in approximately equal numbers (50% to 80% polymorphonuclear, the remaining cells mononuclear) then the response is termed mixed. When mononuclear cells predominate (greater than 50% of the inflammatory cells present) the reaction is classified as macrophagic (nonsuppurative, histiocytic).

Many inflammatory reactions can be even further subdivided on the basis of morphology of the various cell lines. The purpose of subclassification is to provide information regarding pathogenesis of the reaction and to aid in the identification of etiology. A detailed summary of the different classes and subclasses of inflammatory reactions is found in Table 1.

NEUTROPHILIC INFLAMMATION

Neutrophilic inflammation has two subtypes: neutrophilic with nondegenerate neutrophils, and neutrophilic inflammation with degenerate neutrophils. Nondegenerate neutrophils are either morphologically similar to those of peripheral blood or exhibit nuclear hypersegmentation. Degenerate neutrophils have characteristic nuclear and cytoplasmic changes.

Nuclear changes in degenerate neutrophils include hyalinization and selling of nuclei (an early stage of karyolysis), pyknosis, karyorrhexis, and karyolysis. Pyknotic nuclei are intensely stained and homogeneous without internal chromatin patterns. Karyorrhectic nuclei are generally pyknotic and have been fragmented into small pieces. Karyolysis is the process of spontaneous dissolution of the nucleus and is recognized as the streaming of nuclear chromatin away from the nucleus into the cytoplasm. Karyolysis can only be recognized in intact cells.

Cytoplasmic features of degeneration in neutrophils are generally more subtle than nuclear features. The cytoplasm becomes homogeneous, glassy and somewhat basophilic.

Neutrophilic inflammation with nondegenerate neutrophils is the result of severe irritation. In most cases, etiologic agents are not observed and the aspirated material will be sterile upon cultural examination. Classification of a reaction as neutrophilic with nondegenerate neutrophils is based upon the morphology of the majority of neutrophils; occasional dead neutrophils with pyknotic and karyorrhectic nuclei are expected even in the purest response.

Neutrophilic inflammation with degenerate neutrophils indicates that there is not only severe irritation but also that there is destruction of neutrophils. Of all the degenerative changes, nuclear hyalinization and swelling and karyolysis are the most significant because they indicate acute cell death. Acute cell death in neutrophils results for the effects of local toxins. The most common toxins are bacterial, and whenever karyolysis is present sepsis should be suspected even if bacteria are not seen. Culture of these samples is always recommended.

MIXED AND MACROPHAGIC INFLAMMATION

Like neutrophilic inflammation, mixed or macrophagic inflammatory reactions may also be subclassified based upon the morphology of their neutrophils. Interpretation of neutrophil degeneration in these instances is the same as for neutrophilic reactions. In general, however, mixed or macrophagic reactions imply less severe irritation than neutrophilic reactions and the neutrophils are usually either nondegenerate or only mildly degenerate. Of greater importance than neutrophil morphology in mixed and macrophagic inflammation is macrophage morphology.

Typical microphages are large, round to oval cells (20–35 μm) with eccentric round to oval or irregular nuclei. Nuclei have a lacy or reticulate chromatin pattern. Cytoplasm is abundant, granular, and faintly eosinophilic. Cytoplasmic vacuoles are present and generally contain phagocytized material. Phagocytized material is in most cases indistinct cellular debris or RBCs; however, in some instances, specific etiologic agents may be observed.

If all macrophages are of this typical morphology then mixed or macrophagic inflammatory reactions cannot be further classified. However, many mixed inflammatory responses also contain epithelioid cells, inflammatory giant cells, or both. Epithelioid cells are morphologically similar to typical macrophages except that their cytoplasm contains either no or only small vacuoles, and phagocytized material is absent. Inflammatory giant cells are large, multinucleated macrophages, which may contain phagocytized material or have cytoplasm resembling that of epithelioid cells. Nuclei are discrete, typical macrophage nuclei and may be located peripherally at the cell margin or aggregated centrally.

Whenever epithelioid and/or inflammatory cells are present, a mixed or macrophagic reaction can be further classified as pyogranulomatous or granulomatous, depending upon the prevalence of neutrophils. Whereas classification of a response as mixed or macrophagic suggests nothing specific regarding etiology and may be

Table 1. Subclassification of Inflammatory Reactions

Type of Inflammation	Primary Cytologic Feature	Morphologic Subtypes	Interpretation and Etiologic Significance
Neutrophilic	>80% neutrophils	1. With nondegenerate neutrophils	Severe irritation
		2. With degenerate neutrophils	Severe irritation; often septic
Mixed	50–80% neutrophils remaining cells mononuclear	1. With epithelioid cells and/or inflammatory giant cells (pyogranulomatous)	Low-grade irritant; consider foreign body, systemic mycoses, actinomycotic infection
		2. Without epithelioid cells and/or inflammatory giant cells (nonspecific)	Resolving neutrophilic/ eosinophilic reaction; low-grade irritant
Macrophagic	>50% macrophages	1. With epithelioid and/or inflammatory giant cells (granulomatous)	Low-grade irritant; consider foreign body, systemic mycoses, actinomycotic infection
		2. Without epithelioid and/or inflammatory giant cells (nonspecific)	Resolving neutrophilic/ eosinophilic reaction; low-grade irritant
Eosinophilic	Moderate to high numbers of eosinophils, other cells vary with subtype	1. With neutrophils	Allergic reaction
		2. Mixed	
		3. Granulomatous	

associated with resolving neutrophilic inflammation as well as with more traditional causes of low-grade irritation, classification as pyogranulomatous or granulomatous suggests that a foreign body, mycotic, actinobacterial or mycobacterial etiology should be considered. Often, these etiologic agents can be demonstrated cytologically.

EOSINOPHILIC INFLAMMATION

Inflammatory reactions characterized by noticeable numbers of eosinophils are generally the result of allergic phenomena and merit separate consideration. Causes include parasitic disease, mast cell tumors, asthma and systemic atopic responses. Eosinophils are rarely the principal cell seen; rather, they represent a prominent accompaniment of a neutrophilic, macrophagic or mixed inflammatory reaction. Eosinophils in these responses may be quite transient; we have seen a number of parasitic diseases where treatment resulted in a disappearance of eosinophils from the reaction in as few as 48 to 72 hours. Indeed, in these instances, abatement of the eosinophil numbers is a useful index of response to therapy.

IMPORTANT CONSIDERATIONS IN THE CYTOLOGIC EVALUATION OF INFLAMMATION

Several points regarding cytologic classification of inflammation are worthy of emphasis at this juncture. First, numbers of the various inflammatory components are always estimated, never counted. Uneven distribution of cells in cytologic specimens makes counting differentials unreliable. Second, inflammatory cytology should not be regarded primarily as an indicator of lesion duration but rather is best regarded as an indicator of the level of tissue irritation. Type of inflammation often provides significant help in identifying underlying etiology. Finally, inflammatory cytology also has utility in following the course of an inflammatory reaction or the response to therapy.

Consider the horse with an acute volvulus. Cytologic evaluation of the peritoneal fluid is commonly used to gauge the stage and severity of the reaction in such patients. The primary problem for the animal with volvulus is ischemia of the gut with eventual ischemic necrosis. Early in the disease, reduced blood flow leads to severe irritation of the involved bowel segment. At this stage cytologic evaluation of peritoneal fluid reveals neutrophilic inflammation with nondegenerate neutrophils and the prognosis for surgical intervention is good. If correction does not occur at this stage, the condition will likely worsen. Stasis of intestinal contents leads to bacterial proliferation and turnover with the release of bacterial toxins. These toxins can seep through the intestinal wall in to the peritoneal cavity. At this stage peritoneal fluid cytology reveals neutrophilic inflammation with degenerating neutrophils and prognosis for surgical corrections is only fair.

With continued hypoxia, integrity of the bowel wall becomes increasingly compromised until ischemic necrosis begins. At this stage, bacteria from the bowel gain access to the peritoneal cavity. Initially, the majority of these organisms are quickly phagocytized by neutrophils containing bacteria, or septic peritonitis. Prognosis is guarded. Advancing necrosis results in freer access of organisms to the cavity until the capacity of the inflammatory response to contain the bacteria is overwhelmed. This is reflected cytologically by the presence of a variety of types of bacteria both free in the background of the slide as well as within the cytoplasm of severely degenerate neutrophils. Such a finding cytologically dictates a poor to unfavorable prognosis; these animals generally do not recover.

CYTOLOGY OF BLOOD

John W. Harvey, DVM, PhD, Diplomate ACVP
College of Veterinary Medicine
University of Florida, Gainesville, FL

Alan H. Rebar, DVM, PhD, Diplomate ACVP
Discovery Park, Purdue University, West Lafayette, IN

Blood films are generally examined following methanol fixation and staining with Romanowsky-type stains such as Wright or Wright-Giemsa. Rapid stains such as Diff-Quik are satisfactory, but are generally not of as high quality as Wright or Wright-Giemsa stains. These blood stains allow for examination of erythrocyte, leukocyte and platelet morphology. The new methylene blue wet mount stain or a reticulocyte stain is needed to stain for reticulocytes and Heinz bodies. For veterinarians who perform CBCs in their practices, it is essential that they and/or their technician are competent in the examination of stained blood films. Even when veterinarians send their CBCs to a commercial laboratory, the examination of stained blood smears can provide fast, useful information in emergency and after-hours situations.

It is important that an organized approach be made when examining a blood smear so that maximal information can be obtained. The smear is scanned initially at low magnification to estimate the total leukocyte count and to examine for the presence of large platelet aggregates, low numbers of abnormal cells, and microfilaria that might be missed during the differential count. One should always examine the feathered end of glass slide smear preparations since platelet aggregates, large cells, microfilaria, and sometimes leukocytes, tend to be pushed out and concentrated at the end of the slide. We estimate the total blood leukocyte count (cells/µL) by determining the average number of leukocytes per field using 10x or 20x objectives and multiplying by 150 or 500, respectively. For example, if 100 cells were counted per field using the 10x objective, the estimated total leukocyte count would be 100 x 150 = 15 $\times 10^3$/µL. These factors may need to be modified depending on the microscope used. With experience, one can look at stained blood films and get a rough estimate of cell numbers without actually counting the cells. These estimates provide useful information when an automated cell count is not available and provide a source of quality control when an automated cell count is also done.

After the leukocyte count is estimated, a differential leukocyte count is done using a 40x or 50x objective. It is the absolute number of each leukocyte type that is present, not the percentage that is important. Relative values (percentages) can be misleading if the total leukocyte count is abnormal. As an example let us consider two dogs, one with 7% lymphocytes and a total leukocyte count of 40,000/µL and one with 70% lymphocytes and a total leukocyte count of 4,000/µL. The first might be classified as a relative lymphopenia and the second as a relative lymphocytosis, but both cases, in fact, have the same normal absolute lymphocyte count (2,800/µL).

The presence of a high neutrophil count does not necessarily indicate inflammation, since neutrophilia may occur from epinephrine release and endogenous or exogenous glucocorticoids. The presence of a lymphopenia, an eosinopenia and, in the dog, a monocytosis along with a neutrophilia is indicative of stress or exogenously administered glucocorticoids. Significant left shifts do not occur with glucocorticoid or epinephrine-induced (physiologic) neutrophilia; consequently, the presence of a left shift is usually indicative of purulent inflammation. However, some noninfectious conditions (eg, autoimmune hemolytic anemia in dogs) may also have an associated left shift. The presence of toxic cytoplasm (foamy basophilia and/or Döhle bodies) along with a left shift is suggestive of a primary or secondary bacterial infection. It is beyond the scope of this presentation to consider all abnormal leukogram patterns. Suffice it to say that much information can be gained from a differential leukocyte count.

Following the differential leukocyte count, one should examine erythrocyte morphology and evaluate the number and morphology of platelets present using the 100x objective. While rouleaux formation of erythrocytes is normal in cats, prominent rouleaux formation in dogs is most often an indicator of the presence of an inflammatory process.

If an animal is anemic, it is especially important to evaluate blood smears for the presence of polychromasia. Most canine reticulocytes and the aggregate reticulocytes of cats will appear blue to bluish-red when properly stained with routine blood stains. Increased polychromasia provides evidence of a regenerative response to anemia and indicates that the anemia is the result of either blood loss or increased erythrocyte destruction. A lack of polychromasia indicates a lack of bone marrow response in the dog, which may be the cause of the anemia. In mild anemia in cats, punctate reticulocytes may be released from the bone marrow without an accompanying release of aggregate reticulocytes. Since punctate reticulocytes contain insufficient RNA to make these cells appear polychromatophilic with routine blood stains, a lack of polychromasia does not necessarily indicate a nonregenerative anemia in mildly anemic cats. If staining is not optimal, it may be difficult to determine the degree of polychromasia. In this case, a reticulocyte stain should be prepared to determine if a reticulocytosis is present.

The presence of various erythrocyte shape abnormalities may provide information concerning the cause of an anemia or nature of the disease process present. For example, the presence of frequent spherocytes in dogs indicates the likelihood of an immune-mediated hemolytic process. The presence of schistocytes, along with decreased platelets, in dogs suggests that disseminated intravascular coagulation may be present. The presence of acanthocytosis, polychromasia and frequent nucleated erythrocytes in dogs should result in hemangiosarcoma being placed high on the list of differential diagnoses. The presence of unstained "spots" and/or nipple-like projections in erythrocytes may indicate the presence of Heinz bodies. When Heinz bodies are suspected, it is wise to verify their size and number using a reticulocyte stain. Cats may have up to 5% small to medium Heinz bodies normally, and increased numbers may occur in association with certain metabolic disorders and in cats eating soft-moist cat foods containing propylene glycol. Consequently, the finding of Heinz bodies in cats does not necessarily indicate drug-induced oxidant injury. In addition to Heinz bodies, oxidant-induced injury to canine erythrocytes may result in the formation of eccentrocytes (erythrocytes where the hemoglobin is concentrated to one side of the cell).

The presence of hypochromic-appearing erythrocytes is strongly suggestive of iron deficiency. This conclusion is supported by finding a low mean cell volume (MCV) and confirmed by finding a low serum iron concentration and normal or increased total iron binding capacity. With the exception of nursing animals, nearly all cases of iron deficiency result from chronic blood loss. Although not specifically diagnostic for lead poisoning, the presence of basophilic stippling, especially when accompanied by circulating nucleated erythrocytes, is highly suggestive of this toxicity.

Various infectious agents including hemotrophic mycoplasmas, *Babesia*, *Ehrlichia*, and *Anaplasma* organisms may be seen in stained blood films. It is important to differentiate organisms from stain artifacts, Howell-Jolly bodies and platelets overlying erythrocytes. Generally bacteria occur in too low of numbers in bacteremia to be found on blood smears. When found, it is important to determine that they are not stain contaminants.

Blood smears from dogs and cats normally average between 12 and 35 platelets per field when examined using the 100x objective. We generally estimate their numbers by multiplying the average number per 100x field by 15,000 to get the number of platelets x10^3/µL of blood. For example, if about 15 platelets are present in each 100x field, the estimated platelet count would be 15 x 15,000 = 225 x10^3/µL. While special attention will be given to the estimation of platelet numbers in animals with hemostatic diatheses, it is important to routinely estimate the platelet numbers on blood films, because many animals with thrombocytopenia exhibit no evidence, or past history, of bleeding tendencies. If a thrombocytopenia is suspected, it should be confirmed with a platelet count. The presence of frequent large platelets in association with a thrombocytopenia suggests that the thrombocytopenia probably results from destruction or utilization rather than decreased production. A major exception to this statement is that platelets may be large in association with myeloproliferative disorder where their production is defective.

CYTOLOGY OF INTERNAL ORGANS

John W. Harvey, DVM, PhD, Diplomate ACVP
College of Veterinary Medicine
University of Florida, Gainesville, FL

Alan H. Rebar, DVM, PhD, Diplomate ACVP
Discovery Park, Purdue University, West Lafayette, IN

Exfoliative cytology can be obtained using imprints of tissues excised during surgical procedures. This provides rapid information (and occasionally details not recognized in histologic sections), but generally more definitive information is obtained by fixing excised tissue in formalin and submitting it for embedding, sectioning, staining with H&E, and evaluation by a veterinary pathologist. The major advantages of histologic sections are that tissue architecture is preserved and more cells are usually available for examination. In addition to more rapid information, fine needle aspirate cytology involves less cost to the client and less trauma to the animal. In the past, high quality exfoliative cytology samples could be obtained from internal organs by fine needle aspiration if the tissue/lesion was large and palpable and the pathologic changes were uniformly distributed. If the tissue or organ to aspirate was small (eg, enlarged adrenal gland) or lesions were focal within a tissue or organ (eg, focal tumor metastasis to the lungs), fine needle aspiration often failed to yield diagnostic material. The availability of ultrasound machines and training in the use of these machines has greatly facilitated the collection of diagnostic, ultrasound guided aspirates of internal organs.

CELLULARITY AND TISSUE OF ORIGIN

Aspirate smears are generally prepared using a squash technique and stained with a Wright-type stain. It is important to note the cellularity (non-blood cells) of the samples obtained and the degree of blood contamination. Few non-blood cells are normally present in tissue aspirates from some organs such as lung and kidney, but many cells are normally present in aspirates from other organs such as liver and lymph nodes. Aspirates from liver and spleen naturally have large amounts of blood contamination not found to the same degree in high quality aspirates from other organs. If increased numbers of leukocytes are present, it is important to make sure they exceed the number present in blood before inflammation is diagnosed. For this reason, it is helpful to have a recent complete blood count (CBC) for comparison.

In addition to overall cellularity, one should identify the types of cells present and determine whether their morphology is consistent with the organ one is trying to biopsy. For example, if a lymph node is enlarged, are sufficient lymphocytes present to allow confirmation that the lymph node was successfully biopsied? Fine needle aspirates may be obtained from a variety of internal organs. This article discusses cytologic examination of aspirate smears for lung, liver, and lymph nodes.

CYTOLOGY OF LUNG ASPIRATES

Aspirates of healthy lung tissue have scant cellularity and variable amounts of blood contamination. Low numbers of respiratory epithelial cells are generally seen. Epithelial cells are cuboidal to columnar with light blue cytoplasm. Nuclei are generally oval with granular chromatin and located in the basilar end of the cell. Cilia may be present on the apical end of some columnar cells. Mucus-secreting goblet cells containing pink to purple cytoplasmic granules may be seen and sparse reddish ribbons of mucus may be present. Low numbers of pulmonary macrophages are a normal finding. When activated, they become large and heavily vacuolated and exhibit phagocytosis of cells and/or debris. Sheets of mesothelial cells are sometimes seen as a result of the needle penetrating serosal surfaces. They are cohesive, angular in shape, and uniform in size. Hepatocytes may also be present if the needle is inserted caudally in the chest and the diaphragm is penetrated.

A cellular lung aspirate is abnormal. Inflammation is indicated when increased numbers of inflammatory cells are present. Neutrophils and macrophages are most often seen, but variable numbers of eosinophils, lymphocytes, plasma cells, mast cells, and basophils may be present. When neutrophils predominate, the sample should be examined closely for infectious agents (especially bacteria), particularly if the neutrophils are degenerate. However, neutrophilic inflammation can also be present in other infectious disorders and noninfectious disorders including neoplasia, necrosis, and foreign body pneumonia.

Activated macrophages can have an epithelioid appearance and form aggregates. These epithelioid macrophages and multinucleate giant cells are characteristically found in granulomatous inflammation. When neutrophils are also prominent, the inflammation is referred to as pyogranulomatous inflammation. Causes of granulomatous or pyogranulomatous inflammation include fungal infections (including aspergillosis, blastomycosis, histoplasmosis, and coccidioidmycosis) and foreign body reactions.

When eosinophils compose more than 10% of the nucleated cells in lung aspirates, parasitic (including heartworms and lungworms) and hypersensitivity processes should be considered. When eosinophils are increased, on should examine a blood films to verify that the increase in not simply from blood contamination. Idiopathic eosinophilic granulomatosis (characterized by increased numbers of eosinophils and variable numbers of macrophages, neutrophils, plasma cells and basophils) occurs in dogs. Mixed inflammatory reactions occur in animals with protozoal (*Toxoplasma gondii* and *Neospora caninum*) pneumonia.

Hemorrhage may be indicated by the presence of erythrophagocytosis, hemosiderin within macrophages, and hematoidin crystals. The presence of abundant basophilic granular to amorphous material in the background, along with "ghost cells" where nuclear and cytoplasmic detail is lost, indicates that necrosis is present. Necrosis is common in the center of neoplastic and inflammatory disorders; consequently, one should try to obtain material from the periphery of lesions to determine the cause of the necrosis.

Neoplasia in lungs may be primary or metastatic, with the latter being more common. Cohesive clusters of basophilic anaplastic epithelial cells occur in carcinomas of lungs, as well as metastatic carcinomas other organs such as prostate, mammary gland, and bladder. With the exception of squamous cell carcinoma, it is generally not possible to determine the site of origin by the morphology of cells alone. Increased eosinophils may occur in dogs with bronchoalveolar carcinoma.

Cells from sarcomas are less cohesive than cells from carcinoma; therefore, they are often seen as individual elongated or spindle-shaped cells. Primary sarcomas in lungs, including osteosarcoma, fibrosarcoma, rhabdomyosarcoma, and schwannoma, are rare in dogs and cats; however, sarcomas from other organs can metastasize to the lungs.

Hemolymphatic neoplasms may be present in lungs, with lymphoma being most common. Malignant histiocytosis occurs in the lungs of dogs (especially Bernese Mountain dogs, golden retrievers, and flat-coated retrievers), but the lung is not a common site in cats. Lymphomatoid granulomatosis is a T-cell tumor in dogs that consists of large pleomorphic mononuclear cells together with infiltrates of lymphocytes, plasma cells, and eosinophils. Neoplastic cells may be in a minority, making it difficult to differentiate this disorder from inflammation (eg, eosinophilic granulomatosis).

CYTOLOGY OF LIVER ASPIRATES

Hepatocytes are the predominant cell type present in normal liver aspirates. These large epithelial cells have low nuclear to cytoplasmic ratios. Their nucleus contains a nucleolus that is sometimes prominent, and their cytoplasm often contains greenish black pigment that is predominantly lipofuscin. Intranuclear crystal-like rectangular structures may be present, especially in aged dogs. Normal hepatocytes are occasionally binucleated. Occasional clumps of small biliary epithelial cells with high N:C ratios and low numbers of mast cells may be observed. Sheets of angular, uniform mesothelial cells are sometimes seen as a result of the needle penetrating serosal surfaces. They must be differentiated from clumps of biliary epithelial cells and carcinomas.

Hepatocyte morphology can change with alterations in metabolism or in response to injury. The presence of discrete vacuoles in the cytoplasm of hepatocytes indicates the presence of lipid, which can fill the cytoplasm in hepatic lipidosis (a common disorder in cats). The presence of cytoplasmic rarefaction (cytoplasmic clearing or nondiscrete “foamy” vacuolation) indicates the accumulation of glycogen or water (hydropic degeneration). Endogenous hyperadrenocorticism and the exogenous administration of glucocorticoids result in the accumulation of glycogen within the liver. When glycogen accumulation is marked, it can result in hepatomegaly. This corticosteroid-induced hepatopathy is common in dogs. Hepatocellular injury, such as toxic insults and hypoxia, can result in hydropic (ballooning) degeneration, in which water accumulates following alterations to cell membranes and cytoplasmic organelles.

The presence of black ribbons of inspissated bile between hepatocytes indicates the presence of cholestasis, and increased numbers of macrophages containing black pigment generally indicate the presence of hemosiderosis.

Because of the substantial blood contamination associated with liver aspirate smears, it can be difficult to determine if inflammation is present. It is helpful to review a CBC collected on the same day to determine whether an increase in a specific cell type represents an inflammatory infiltrate or reflects an increased cell count in blood. The finding of inflammatory cells within clumps of hepatocytes provides evidence for inflammation. Neutrophilic inflammation may be seen in septic inflammation, nonseptic inflammation (eg, acute pancreatitis), and feline neutrophilic cholangiohepatitis. The cause of feline neutrophilic cholangiohepatitis is unknown but may be associated with extrahepatic diseases, including inflammatory bowel disease and acute pancreatitis. Increased numbers of small lymphocytes (and few plasma cells) is a common finding in older cats with lymphocytic portal hepatitis. The frequency with which this inflammatory process causes illness is unknown. A mixed inflammatory response including neutrophils and variable numbers of macrophages and lymphocytes is seen in cats with feline infectious peritonitis. Mixed cell inflammatory reactions may also occur in dogs and cats with fungal, protozoal, and mycobacterial infections. Eosinophils may be a prominent infiltrate in animals with eosinophilic enteritis, and in cats with hypereosinophilic syndrome and liver flukes.

Nodular regenerative hyperplasia of unknown etiology is common in aged dogs. Hydropic degeneration may be present in hepatocytes and variably increased numbers of inflammatory cells, including neutrophils, lymphocytes, and macrophages containing pigment and/or lipid, may be observed. Extramedullary hematopoiesis, especially involving granulopoiesis, may occur as a nonspecific reaction to nodular reactive hyperplasia and other chronic hepatic disorders in dogs.

The observation of ribbons of eosinophilic material associated with hepatocytes suggests the presence of amyloid deposits. Systemic amyloidosis occurs secondary to chronic extrahepatic inflammation. It appears to be a familial disease in Chinese shar pei dogs and Abyssinian and Siamese cats.

Primary hepatic neoplasia includes hepatocellular adenoma or hepatoma (with relatively normal-appearing hepatocytes), hepatocellular carcinoma (with mildly to markedly abnormal hepatocytes), and bile duct adenomas and carcinomas (both of which usually have relatively normal appearing bile duct epithelial cells). Hepatocellular neoplasms are more common in dogs and bile duct neoplasms are more common in cats. The liver is a frequent site of metastasis for hematopoietic neoplasms including lymphoma, lymphoid leukemias, myeloid leukemias, mast cell tumors, and malignant histiocytosis. In addition, carcinomas and sarcomas from the intestinal tract and pancreas often metastasize to the liver because of vascular drainage from these organs.

CYTOLOGY OF LYMPH NODE ASPIRATES

Lymphocytes are fragile and easily lysed during smear preparation; consequently, aspirate smears exhibit variable numbers of free nuclei and cytoplasmic vesicles (lymphoglandular bodies). Small lymphocytes (1–1.5 times the diameter of a RBC), account for 90% or more of the total nucleated cells in normal lymph nodes. Medium (2–2.5 times the diameter of a RBC) and large (>3 times the diameter of a RBC) lymphocytes account for 5% to 10% of the total nucleated cells in normal lymph nodes. Small lymphocytes have densely clumped nuclear chromatin and scant cytoplasm, and medium and large lymphocytes have less densely clumped nuclear chromatin, and variable amounts of cytoplasm. Nucleoli may be visible in some of these immature cells. Plasma cells, macrophages, and neutrophils may be present in low numbers, and rare mast cells may be seen. Perinodal fat may be present on the smear. Salivary epithelial cells may be present if the salivary gland is aspirate by mistake instead of a submandibular lymph node.

Reactive lymphoid hyperplasia occurs in response to local or generalized antigenic stimulation associated with septic or nonseptic inflammation and neoplasia in areas drained by the lymph nodes. Small lymphocytes predominate, but medium/large lymphocytes increase up to 15% of all nucleated cells, and plasma cells increase slightly to markedly in numbers. Slight increases in neutrophils, macrophages, or eosinophils may also be present. Idiopathic peripheral lymphadenopathy in young cats is an exception to the pattern described above. Medium/large lymphocytes predominate, mimicking a lymphoma. Spontaneous regression of the lymphadenopathy occurs over a period of weeks to months. A majority of cats are reported to be FeLV positive.

The term *neutrophilic lymphadenitis* is used when neutrophils exceed 5% of all nucleated cells in a smear with minimal blood contamination. Neutrophils may be increased in response to septic, nonseptic, and neoplastic disorders. The term *eosinophilic lymphadenitis* is used when eosinophils exceed 3% of all nucleated cells. Eosinophils may be increased in response to eosinophilic inflammation (eg, flea-bite hypersensitivity and feline rodent ulcers), hypereosinophilic syndrome, and as part of a paraneoplastic reaction to mast cell tumors (especially dogs) and less often certain lymphomas and carcinomas. Increased macrophages and multinucleated giant cells in granulomatous or pyogranulomatous inflammation occur in response to certain fungal, protozoal, protothecal, mycobacterial, and rickettsial disorders.

A wide variety of tumors metastasize to regional lymph nodes. Clusters of carcinoma cells are more easily recognized than individual round cells or sarcoma cells. Neoplastic lymphocyte infiltrates can be confused with reactive lymphoid hyperplasia if the neoplastic cells account for a minority of the total lymphocytes present.

Most lymphomas in dogs and cats are high-grade lymphomas consisting of medium to large neoplastic lymphocytes, that generally comprise 60% to 90% of all the nucleated cells. Lymphomas with lower numbers of neoplastic cells and low-grade lymphomas involving small lymphocytes may be difficult to recognize in aspirate smears. Lymphomas are classified in various ways using architecture on histopathology, lymphocyte morphology, and immunophenotyping (B cell versus T cell). It is not possible to definitively separate B-cell lymphomas from T-cell lymphomas by morphology alone, although some B-cell lymphomas have a plasmacytoid appearance and T-cell lymphomas may have more pleomorphic or convoluted nuclei.

CHEMISTRY: PROFILING AND TRENDING

Alan H. Rebar, DVM, PhD, Diplomate ACVP
Discovery Park, Purdue University, West Lafayette, IN

Biochemical profiling is defined as the use of multiple blood chemistry determinations to simultaneously assess the health status of various organ systems. In addition to standard chemistry tests, other parameters (ie, hemograms, urinalysis) are measured to give a more accurate and complete picture of the overall health status of the patient. Strictly speaking, hemograms and urinalysis are not part of clinical biochemical profiles; however, biochemical profiles cannot be accurately interpreted without simultaneous evaluation of the complete blood count (CBC) and urinalysis.

Biochemical profiling is a powerful diagnostic and monitoring device used in ill patients and those receiving therapy. It is also an important component of regular wellness evaluations in healthy dogs and cats. Although biochemical profiling offers exciting potential as a clinical tool, it is not a panacea. The following paragraphs illustrate some of the more important difficulties encountered in the interpretation of clinical chemistry data.

Since standard chemistry screens may include from 12 to 30 different test results, interpretation of these data may be extremely complex. Furthermore, interpretation of results is often clouded by the fact that perfectly normal animals may have—indeed are expected to have—an occasional abnormal test result. It is estimated that in a standard panel of 12 chemistry tests, approximately 46% of all normal subjects will have at least one abnormal test result. Such abnormalities are usually associated with the way in which referenced (or normal) values are determined.

In order to establish the “normal range” reference values for a given test, the procedure is performed on samples from a large population of clinically normal individuals. The central 95% of the given results is identified and, if the data have a Gaussian distribution, a mean and a standard deviation are determined based on the central 95%. The reference values are then defined as those values falling within the central 95%, ie, within two standard deviations above and below the mean. Therefore, 5% of the values from a normal (ie, healthy) population fall outside the defined “normal” reference interval for any given parameter.

Just as healthy individuals may have occasional abnormal test results, patients with severe organ disease can have test results that lie within the normal reference intervals. For example, elevated alanine aminotransferase (ALT)—an enzyme normally found in the cytosol of hepatocytes—has long been considered an important indicator of liver disease in dogs. However, serum ALT levels will only be elevated under specific circumstances, eg, in conditions where there is injury to hepatocyte plasma membranes causing release of cytoplasm from membrane-bound vesicles. In more chronic liver disease, plasma membrane characteristics may be near normal. In addition, ALT levels reflect the number of hepatocytes with injured membranes; therefore, marked elevations are more commonly seen in diffuse rather than localized liver disease. ALT levels also will vary with the stage of organ disease at the time of sample collection. This enzyme has a circulating half-life of 2 to 4 days; therefore, a 2-fold elevation in ALT due to acute liver necrosis may be expected to return to near normal within a week.

The clinician must also be aware that physical compromise of one organ system may cause abnormal chemistry value sin tests that are used primarily to indicate disease in a different organ system. For example, calcium levels are used primarily as indicators of parathormone activity. However, serum calcium is partially bound to albumin filtrate. Consequently, anything that reduces albumin concentration may result in reduced calcium concentration, which could lead to erroneous conclusions about parathormone activity.

Key points in the practice of biochemical profiling:

- A single chemistry test should never be used to assess the total health status of an organ.
- Understand the factors affecting a given test results, such as the causes of elevations, circulating half-lives of components being measured, and routes of excretion.
- Consider the interactions between different organ systems and how the interaction can affect various test results.
- Only through the systematic assessment of data can misinterpretation and confusion be avoided.

Another key to understanding chemistry organ panels is to interpret them as a part of a larger laboratory profile that includes hemogram evaluation (the CBC) and urinalysis. The CBC and urinalysis provide general information regarding the patient. These should be interpreted first. The remainder of the chemistry panels assesses various organ systems and are best interpreted last.

The CBC includes white cell data, red cell data, platelet data, and total plasma protein. Leukogram data provide information regarding the presence of inflammation, stress, tissue necrosis, antigenic stimulation, systemic hypersensitivity or systemic toxemia. Erythrogram data provide information regarding the presence of anemia or polycythemia and also allows the classification of these syndromes into pathophysiologic subtypes. Platelet data indicate presence or absence of thrombocytopenia, which can be caused by destruction (immune-mediated), consumption (disseminated intravascular coagulation), or lack of production, or sequestration (hypersplenism). Increased total plasma protein suggests either hemoconcentration from dehydration or possible antigenic stimulation. Decreased plasma protein suggests loss through the gastrointestinal system, kidney, or blood loss or possible reduced protein production by the liver.

Complete urinalysis includes physical examination, chemical examination, and sediment examination. The complete urinalysis provides data regarding renal tubular concentrating ability, renal tubular integrity, urinary tract hemorrhage/infection, ketoacidosis, and cholestasis.

A final aspect of biochemical profiling is consideration of the value of trending. *Trending* refers to the evaluation of multiple chemistry panels over time in the same patient. Trending is of value both in health and disease. In healthy animals, trending provides a more personalized reference range, which can be used to recognize subtle changes as they occur with aging. In diseased animals, trending is used to gauge the progress of response to therapy.

GENERAL APPROACH TO CYTOLOGIC INTERPRETATION

Alan H. Rebar, DVM, PhD, Diplomate ACVP

John W. Harvey, DVM, PhD, Diplomate ACVP
College of Veterinary Medicine
University of Florida, Gainesville, FL

Once the cytologic specimen has been properly collected and stained, it is ready for examination under the microscope. The principal roles of the cytologist are to recognize and classify inflammatory reactions to identify any etiologic agent that may have caused inflammation, and to recognize the presence of malignant cells. In this article, we discuss the general guidelines that are followed in making such determinations.

SCANNING THE SLIDE

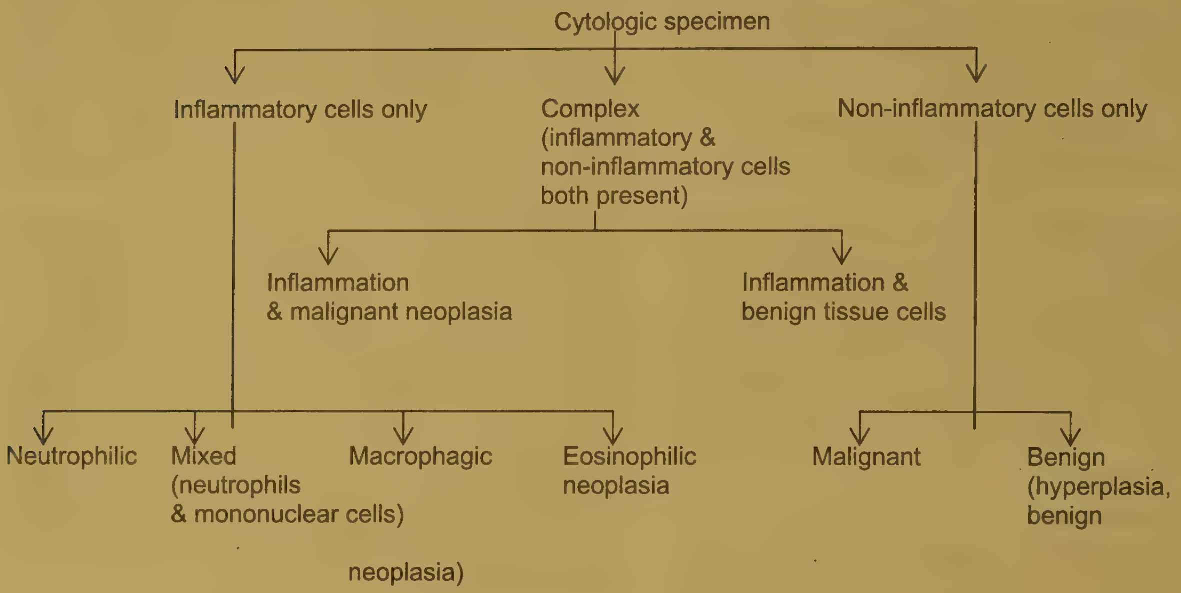
Cytologic interpretation begins with proper slide evaluation. Different kinds of specimens demand different approaches. For example, fluid smears are made in the same manner as peripheral blood films and consequently have a thick area (near the point of specimen application), a monolayer (towards the center of the smear) and a feathered edge (area most distant from the point of application). When fluid smears are examined, all three areas of the smear are evaluated, first at low magnification and later under oil immersion. Each area is examined for different features. For example, the most important area for evaluation of cell morphology is the monolayer. Large particulate material, large cells, or cells containing phagocytized material are generally found either in the thick portion of the smear or at the feather edge. Consequently, in the case of inflammatory reactions, classification requires mental integration of the relative numbers of the different cell types seen in the monolayer and at the feather edge. (See the companion article, Cytology of Inflammation, in this proceedings.) Since neutrophils concentrate in the monolayer and macrophages in the feather edge, it is easy to appreciate that examination in only one area can lead to misinterpretation of cytologic response.

Slides made by squashing, scraping, or impression smear techniques also require scanning at low magnification. In these cases, low magnification assessment is done to determine what part of the preparation is best for evaluation of cell morphology under oil. All squashing, scraping, and smearing techniques produce slides that vary in sample quality from area to area. Some areas are too thick to allow evaluation of cytologic detail, while in other areas a majority of the cells are broken. A cardinal rule of cytology is that only intact cells can be interpreted, so finding a monolayer area where cells are intact and cytologic detail can be observed is critical.

Whereas in fluid smears one must be concerned about cell distribution between the monolayer and feathered edge, in scrapings and squash preparations from aspirates this is not an issue because cell distribution is generally random. In contrast, cells in high quality impression smears are not randomly distributed but rather reflect cell distribution in the tissue imprinted. For example, aspirates taken from a reactive hyperplastic lymph node will have a random mixture of small lymphocytes, large lymphoblasts, and plasma cells (from medullary cords). Consideration of cell distribution in impression smears can therefore provide some information regarding tissue structure.

GENERAL APPROACH TO CYTOLOGIC INTERPRETATION

As the slide is scanned, cytologic interpretation begins. Because of the wide variety of specimen sources—effusions, lymph nodes, skin masses, internal organs, etc.— the novice at first may be overwhelmed by the variety of cells encountered. However, the beauty of diagnostic cytologic is that regardless of sample source, the general approach to interpretation is the same. This approach is summarized in the flow chart in Figure 1. Interpretation always begins with the answer to one basic question: How many cell types are present on the slide? Fortunately, there are only three possibilities. Either all of the cells are inflammatory (neutrophils, eosinophils, lymphocytes, plasma cells, or monocyte/macrophages), or all are non-inflammatory (of tissue origin), or the cytologic response is complex (both inflammatory and non-inflammatory). Specific approaches to classifying inflammatory responses and recognizing malignant neoplasia are covered in subsequent manuscripts. (See the companion article Cytology of Inflammation and Cytology of Neoplasia in this proceedings).



Cytologic specimen
Inflammatory cells only
Complex (inflammatory & non-inflammatory cells both present)
Non-inflammatory cells only
Inflammation & malignant neoplasia
Inflammation & benign tissue cells
Neutrophilic
Mixed (neutrophils & mononuclear cells)
Macrophagic
Eosinophilic
Malignant
neoplasia
Benign (hyperplasia, benign
neoplasia)

CYTOLOGY OF NEOPLASIA

Alan H. Rebar, DVM, PhD, Diplomate ACVP

John W. Harvey, DVM, PhD, Diplomate ACVP
College of Veterinary Medicine
University of Florida, Gainesville, FL

CYTOLOGY OF MALIGNANT NEOPLASIA

Neoplastic processes may be either benign or malignant. It is virtually impossible to differentiate between benign neoplasia and hyperplasia cytologically, and these benign processes therefore are discussed together in a later section. Malignant neoplastic processes are identified through the recognition of specific malignant criteria exhibited by the cell population under consideration. Criteria of malignancy may be loosely classified into four categories:

1. General criteria of malignancy
2. Nuclear criteria of malignancy
3. Cytoplasmic criteria of malignancy
4. Structural criteria of malignancy

General criteria of malignancy refer to the appearance of the cell population as a whole. Malignant neoplastic processes are generally characterized as a uniform population of pleomorphic cells; that is, cells usually appear to be of a single cell type (for example, all mast cells or all spindle-shaped connective tissue cells) which exhibit variable cell size and variable nuclear size. These features can generally be recognized at low magnification and represent the first suggestion that the cytologic diagnosis is one of malignant neoplasia. While such pleomorphism in a uniform population of cells is easy to recognize in uncomplicated cases, the presence of large numbers of inflammatory cells may mask neoplasia. Therefore, whenever an inflammatory response is associated with a population of non-inflammatory cells, the non-inflammatory cells should be carefully scrutinized for evidence of malignancy. Inflammatory cells are commonly encountered in large numbers in cytologic preparations from oral or skin neoplasms with ulcerated surfaces.

Nuclear criteria of malignancy are the most important criteria employed in identifying a malignant neoplasm cytologically. Evaluation of nuclei for malignancy is best performed under oil immersion. Features suggesting malignancy (in Romanowsky stained preparations) include multiple nucleoli, large irregularly shaped nucleoli, coarse chromatin patterns (areas within the nucleus which stain intensely as well as other areas which are virtually unstained or only poorly stained), irregularities and indentations in the nuclear membrane and variable nuclear/cytoplasmic ratios among the cells seen. Mitotic figures per se are not a criterion of malignancy as they may be seen in hyperplastic cell populations (eg, lymph node hyperplasia); however, abnormal mitoses (eg, three or more planes of division) are a feature of malignancy. Multinucleated tumor cells are occasionally seen, but giant cells may also occur in inflammatory reactions (granulomatous inflammation). Since the nuclear criteria of malignancy are the most important in establishing the diagnosis of malignant neoplasia, the authors suggest that three to four such nuclear alterations be identified before the diagnosis of malignancy is suggested.

Cytoplasmic criteria of malignancy are considerably less important in establishing a diagnosis of malignant neoplasia but do provide supportive evidence. Cytoplasmic criteria include cytoplasmic basophilia, cytoplasmic vacuolation and variation in amounts of cytoplasm. Cytoplasmic features of malignancy suggest the primitive nature of the neoplastic population; for example, cytoplasmic basophilia results from a high cytoplasmic content of RNA, a constant feature of young proliferating cells.

After the nuclear and cytoplasmic criteria of malignancy have been used to establish the cytologic diagnosis of malignant neoplasia, the structural features of the neoplastic cells may be evaluated in an attempt to further classify the tumor as a carcinoma, sarcoma, or discrete cell neoplasm. Carcinomas are neoplasms of epithelial cell origin. Normal epithelial cells are generally adherent to one another and this property is generally reflected in cytologic preparations from epithelial cell neoplasms. Carcinoma cells are generally round to oval, and are arranged in sheets and clusters. Cells from neoplasms of glandular epithelium (adenocarcinomas) are often arranged in acinar patterns around a central lumen. Adenocarcinoma cells also often contain large vacuoles containing secretory product.

Sarcomas are neoplasms of cells of connective tissue origin. Connective tissue cells generally are embedded in a matrix, which they themselves secrete. Consequently, aspirates or imprints from sarcomatous masses are generally less cellular than cytologic preparations made from epithelial or discrete cell neoplasms. Structurally, connective tissue cells are usually spindle-shaped or flame-shaped (cells with tails) and this morphology is also typical of sarcomatous cells.

The sarcomas of veterinary significance include osteosarcoma, fibrosarcoma, liposarcoma, hemangiosarcoma, melanosarcoma, and chondrosarcoma. Osteosarcoma and chondrosarcoma cells are more commonly flame-shaped than spindle-shaped. In addition, aspirates from these two neoplasms may contain considerable matrix material—eosinophilic osteoid in the case of osteosarcoma and metachromatic (purple) chondroid in the case of chondrosarcoma. The cytoplasmic margin of osteosarcoma cells is often irregular and vacuolated. Melanosarcoma has several distinguishing cytologic features. Of principal importance is the presence of brown to black cytoplasmic granules (melanin) of variable size and shape. In addition, melanosarcomas are often comprised of cells of two shapes—spindle-shaped and round to oval (epithelioid). Fibrosarcoma, hemangiosarcoma, and liposarcoma may be indistinguishable cytologically. All are comprised of basically spindle-shaped cells. Aspirates from hemangiosarcoma usually contain considerably more blood than the other sarcomatous masses. Liposarcoma cells may contain large lipid-filled vacuoles which may be demonstrated with lipid stains such as oil red O or the Sudan stains. Illustrations of the various sarcoma cells can be found elsewhere.

The discrete cell neoplasms constitute a rather large group of tumors of veterinary importance. Included among the discrete cell neoplasms are malignant lymphomas, mast cell tumors histiocytomas, and transmissible veneral tumors. Structurally, discrete cell neoplasms are seen cytologically as neoplasms comprised of individual round or oval cells with no adherence between cells and no ordered arrangement of cells (such as cluster formation). The individual discrete cell neoplasms have distinguishing features, which have been illustrated and described elsewhere.

CYTOLOGY OF BONE MARROW

Alan H. Rebar, DVM, PhD, Diplomate ACVP
Discovery Park, Purdue University, West Lafayette, IN

John W. Harvey, DVM, PhD, Diplomate ACVP
College of Veterinary Medicine
University of Florida, Gainesville, FL

Throughout adult life, all blood cell types are continuously produced from primitive stem cells within extravascular spaces of bone marrow in mammals. Pluripotent hematopoietic stem cells produce pluripotent myeloid progenitor cells, as well as a pluripotent lymphoid progenitor cells. The pluripotent lymphoid progenitor cell gives rise to B lymphocytes, T lymphocytes, natural killer (NK) cells, and lymphoid dendritic cells. Lymphoid cells are also produced within peripheral lymphoid organs. The pluripotent myeloid progenitor cell gives rise to a series of progressively more differentiated progenitor cells that support the production of all non-lymphoid blood cells and some tissues cells (macrophages, myeloid dendritic cells, osteoclasts, and mast cells).

Blood cell production occurs in bone marrow of adult animals because of the unique microenvironment present there. Production of blood cells also requires the presence of specific hematopoietic growth factors that may be produced locally in the bone marrow or produced by peripheral tissues and transported to the marrow via the blood (humoral transport). Changes in growth factor production and/or the marrow microenvironment can have profound effects on blood cell production.

REASONS FOR BONE MARROW EXAMINATION

Bone marrow evaluation is indicated when peripheral blood abnormalities are detected that cannot be explained. The most common indications are persistent neutropenia, unexplained thrombocytopenia, and/or poorly regenerative anemia. The presence of multiple cytopenias indicates the likelihood of bone marrow pathology. Examples of proliferative abnormalities where bone marrow examination may be indicated include persistent thrombocytosis or leukocytosis (especially lymphocytosis), abnormal blood cell morphology, or the unexplained presence of immature cells in blood (eg, nucleated erythroid cells in the absence of polychromasia or a neutrophilic left shift in the absence of inflammation).

Bone marrow is sometimes examined to stage a neoplastic condition (lymphomas and mast cell tumors), estimate the adequacy of body iron stores, evaluate lytic bone lesions, and search for occult disease in animals with fever of unknown origin, unexplained weight loss and unexplained malaise. Bone marrow examination can also be useful in determining the cause of a hyperproteinemia when it occurs secondarily to multiple myeloma, lymphoma, leishmaniasis and systemic fungal diseases. It may also reveal the cause of a hypercalcemia when associated with lymphoid neoplasms, multiple myeloma or metastatic neoplasms to bone.

There are few contraindications for a bone marrow aspiration biopsy. Restraint, sedation, and anesthesia (when used) generally provide more risks to the patient than the biopsy procedure itself. Postbiopsy hemorrhage is a potential complication in patients with hemostatic diatheses, but it rarely occurs. Hemorrhage may occur after the biopsy of animals with monoclonal hyperglobulinemias, but it is easily controlled by placing a suture in the skin incision and applying pressure over the biopsy site. Postbiopsy infection is also a potential complication, but it is highly unlikely if proper techniques are used.

SMEAR PREPARATION AND STAINING

It is important for accurate bone marrow evaluation that smears contain marrow particles (stroma and associated cells). Marrow particles appear as small white grains in aspirates. One useful method to assist in the separation of particles from contaminating blood involves the forcible expulsion of several drops of the marrow aspirate onto one end of a glass slide that is then held vertically. Particles tend to stick to the slide while blood runs off. A second glass slide is placed across the area of particle adherence perpendicular to the first slide and, after marrow spreads between the slides, they are pulled apart in the horizontal plane. Resultant smears are rapidly air dried. Since marrow clots rapidly, one may collect marrow into a syringe that contains several drops of 4% EDTA as an anticoagulant. Marrow is mixed with the anticoagulant and expelled into a weighing dish or petri dish. Particles are then collected by capillary tube or pipette, and squash preparations are made.

Smears are stained with a Romanowsky-type blood stain such as Wright, Giemsa or a combination thereof. Satisfactory results can usually be obtained with the Diff-Quik stain, a rapid modified Wright stain. If adequate smears are available, one smear should be stained using the Prussian blue procedure for iron. Additional special stains may be needed to help differentiate the type of leukemia when present.

BONE MARROW ASPIRATE CYTOLOGY

Bone marrow should be examined and findings recorded in a systematic manner. Smears should be scanned with low-power objectives to gain an appreciation of overall cellularity and determine the adequacy of megakaryocyte numbers. Normal marrow appears heterogenous. As a general rule, erythroid precursors are smaller, have more nearly spherical nuclei with more condensed nuclear chromatin, and have darker cytoplasm than do granulocyte precursors at similar maturation stages. Rubriblasts have deeper basophilic cytoplasm than do myeloblasts, promyelocytes or myelocytes. Consequently, smaller and darker cells, observed by scanning marrow smears at low power, are usually erythroid precursors (unless lymphocytes are increased in numbers) and the larger, paler cells are usually granulocyte precursors.

Complete differential cell counts are not usually done on marrow smears, but rather a number of judgments are made and recorded as presented below.

The cellularity of the marrow is estimated by examining the proportion of cells versus fat present in particles. Marrow particles appear as blue-staining areas when viewed grossly. When examined microscopically, they contain vessels, reticular cells, macrophages, plasma cells, and blood cell precursors. Most particles in normal animals are composed of 1/3 to 2/3 cells. If few or no particles are present on smears, it is not possible to accurately estimate marrow cellularity.

The frequency and morphology of megakaryocytes should be evaluated. Most large particles should have associated megakaryocytes, and normally a majority of megakaryocytes are of the granular, mature type. Increased numbers of immature megakaryocytes or abnormal megakaryocyte morphology (eg, dwarf megakaryocytes) should be noted when present.

The distribution of granulocytic cells should be evaluated to determine whether the series is complete (ie, a normal number of mature granulocytes are present) and orderly. If there are increased proportions of cells in the proliferating pool (myeloblasts, progranulocytes, or myelocytes) compared to the later stages of development, this finding should be noted. Morphologic abnormalities, such as vacuolated cytoplasm, or increased representation of eosinophilic or basophilic series should be noted when present.

The maturation and morphology of the erythroid series should be evaluated to determine if it is complete (frequent polychromatophilic erythrocytes should be present) and orderly. Possible abnormal morphologic findings that should be noted include megaloblastic cells, frequent binucleate cells, and pleomorphic nuclei.

A myeloid to erythroid (M:E) ratio is calculated by examining 500 cells and determining the ratio of granulocytic cells (including mature granulocytes) to nucleated erythroid cells. The M:E ratio is generally between 0.75 and 2.5 in normal dogs and between 1 and 3 in normal cats. One needs to have a knowledge of the overall marrow cellularity, as well as the CBC, to interpret the M:E ratio.

Specific comments should be made about lymphocytes, plasma cells, osteoblasts, and osteoclasts when they appear in increased numbers and/or exhibit abnormal morphology. Normal marrow may contain up to 15% small lymphocytes and 2% plasma cells. Monocytes, macrophages and mitotic cells normally do not exceed 1% to 2% of total nucleated cells present. Osteoclasts and osteoblasts are rarely seen except in young, growing animals. Any abnormal cells such as mast cells, neoplastic cells, or macrophages containing phagocytized cells or infective agents should be described.

The amount of stainable iron present is routinely evaluated using the Prussian blue reaction. Stainable iron is easily found in normal marrow aspirates from most domestic mammals, so long as particles are present. It is decreased or absent in iron-deficient animals and increased in association with hemolytic anemias and the anemia of chronic disease. Normal cat bone marrow does not exhibit stainable iron, so its absence cannot be used to confirm a diagnosis of iron deficiency.

The final step in evaluating a bone marrow aspirate is to provide an interpretation of the cytologic findings in light of the history, clinical findings, CBC, and results from other diagnostic tests and procedures. For example, a high M:E ratio could indicate the presence of either increased granulocytic cells or decreased erythroid cells. Examination of CBC results from blood collected at the same time and an estimate of marrow cellularity usually allows the correct interpretation to be made.

URINALYSIS FOR THE CLINICAL DETECTIVE

Meryl P. Littman, VMD, Diplomate ACVIM
School of Veterinary Medicine
University of Pennsylvania, Philadelphia, PA

COLLECTING URINE

When Should You Collect the Sample?

A urine sample should be collected for examination as part of the annual well-visit as well as anytime a diagnostic workup is done on a sick animal. If you are testing blood for some reason, you should probably test urine, too.

For urinary tract infection (UTI): Collect the sample for urinalysis and culture/sensitivity BEFORE starting antibiotic therapy (so the infection is not masked), and at least 3 days AFTER stopping therapy, to be sure the infection has been cleared. Remember that urine testing is the best way to screen for pyelonephritis in an anorexic or vomiting patient, since blood work or abdominal radiographs may not be that helpful to make the diagnosis. The leukesterase dipstick square too often shows a FALSE NEGATIVE, so you must do urine sediment exams! Dogs and cats with diabetes mellitus, hyperadrenocorticism, or on steroid therapy may have occult UTI without WBC in their sediment, so urine culture/sensitivity may be warranted in these patients even without seeing an active sediment. In animals prone to relapse or reinfection, check urinalysis and culture/sensitivity every 1 to 3 months after antibiotics are stopped.

To check if the animal can concentrate its urine: collect the sample BEFORE starting replacement fluid therapy, to see if the patient is able to concentrate the urine when it is in the partially dehydrated state. In an animal which is not dehydrated, first morning urine is usually the most concentrated urine of the day.

To check whether urinary acidifiers are working throughout the day, take a POST-prandial sample since that is the time of day the urine is most likely to be alkaline (see pH below) even in a carnivore, to see if the acidifier is working even then. To check whether urinary alkalinizers are working throughout the day, take a first morning (or fasted, PRE-prandial) sample, since that is the time of day when the urine is most likely to be acidic in a carnivore and you can check if the alkalinizer is working even at that time.

How Should you Collect the Urine Sample?

Cystocentesis samples are best for urine culture or when looking for evidence of infection in the sediment (bacteria, wbc), but the method is contraindicated if thrombocytopenia or bleeding tendency exists or if bladder cancer is suspected (in which case, a catheterized sample may be better). Cystocentesis is best done with ultrasound guidance if pyometra, prostatic abscess, or ascites is suspected. Catheterization may cause some trauma and if not done with care, increases the risk of introducing organisms into the bladder. Free catch (mid-stream) sampling is often adequate for urinalysis, E.R.D. (HESKA) or microalbuminuria (MA) test, urine protein/creatinine ratio, genetic metabolic screening, veterinary bladder tumor antigen test (V-TBA) and cytology, in other words, most situations except for culture (and possibly sediment, since preputial smegma or vaginal discharge may be misinterpreted as urinary tract infection). Sometimes it is worthwhile to compare free-catch samples to cystocentesis samples, to see if blood, WBC, or protein in a free catch sample may be due to lower genital excretion. Blood may be due to the method of collection. Cystocentesis, catheterization, and even manual expression of the bladder may cause bleeding.

The date, time of day, method of collection, observations concerning micturition, or other notables, such as “pre-fluids” or “pre-antibiotics” should be recorded. If the sample was taken off the floor, note it. The results may still be helpful for some things (USG, or if WBC or RBC are absent), but perhaps not for others, since contamination by disinfectant/cleansing agents from the floor, other exudations/dirt, may cause false results.

Where Should a Free-Catch Sample be Obtained?

If a free catch sample is deemed adequate for the intended test, should the owners try to get the sample from home, or should we get the sample once the animal gets to the hospital? I especially ask for the owner’s help if I want to see a first morning urine specific gravity, a fasted pH level, or if a urine cortisol/creatinine ratio will be done. A urine sample obtained during the hospital visit may show elevations of urine pH due to hyperventilation/anxiety or elevation of the urine cortisol/creatinine ratio due to stress.

Why Should You Do a Urinalysis?

A urinalysis gives additional information that you may not get from bloodwork, imaging, etc. For instance, a vomiting animal may have pyelonephritis or perhaps Fanconi syndrome (possibly genetic, eg, in Basenjis, or perhaps due to exposure to toxins, eg, found in chicken jerky treats in September 2007), and the blood work may be non-remarkable or non-specific. In the above examples, an active urinary sediment, possibly with WBC casts (pyelonephritis), or glycosuria in the face of euglycemia, respectively, will help make the diagnoses. There are many such examples where the urinalysis is a vital part of screening and ruling in/out differential diagnoses.

During a routine wellness examination, screening for proteinuria is recommended. See the 2004 ACVIM Consensus Statement on Proteinuria as well as “The Importance of Looking for Proteinuria” in these NAVC 2008 Proceedings. I recommend private practitioners use the in-house E.R.D. test or the quantitative MA test (Antech Reference Lab) for screening, and to switch over to a urine protein/creatinine ratio if the result is moderate or very high.

What Kinds of Tests Can You Do on Urine?

Besides urinalysis (urine specific gravity, dipstick, sediment), urinary protein testing (E.R.D.), microalbuminuria quantitation (MA), sulfosalicylic acid (SSA), urine protein/creatinine ratio, and urine culture/sensitivity, urine can be tested for many things that reflect the health of organs other than the urogenital system. In very small or anemic animals, getting more urine to test may be easier and safer than taking more blood to test. Urine tests may be a reflection of the health of organs other than the urogenital system, for instance pancreas (diabetes mellitus – glucosuria), adrenals (Addison's - urinary electrolytes; stress or hyperadrenocorticism – urine cortisol/creatinine ratio), liver (bilirubinuria, urine bile acid/creatinine ratio), etc. A urine metabolic screen may help diagnose a genetic abnormality or Fanconi syndrome. Cytology (cytospin examination) and the V-TBA are helpful to screen for neoplastic cells or antigens.

Who Should Do the Urinalysis?

YOU (or your staff) should do a urinalysis, in your facility, on a fresh urine sample, right away! Save some of the sample to send for confirmation of your findings by your outside reference lab. If you obtain the sample aseptically, put 1 to 2 mL in a culture tube for possible culture and sensitivity and use the rest for urinalysis, MA/E.R.D., possible urine protein/creatinine ratio, urine metabolic screen, etc. as appropriate for the case. If you have to refrigerate the sample before testing, be sure to allow it to come to room temperature before doing the dipstick examination.

GROSS URINE CHARACTERISTICS

Urine color, clarity, smell, and presence of flocculent material can all be important observations and must be noted. Observation of micturition for dysuria may be helpful, and if blood is grossly present, to note whether it is seen initially, at the end, or throughout the urine stream.

URINE SPECIFIC GRAVITY (USG)

The USG is normally read using a refractometer comparing the urine to water. Dogs and cats may dilute and concentrate urine over a wide range (dogs 1.001–1.070; cats 1.001–1.080). Consistently hyposthenuric, isosthenuric, or fixed USG <1.025 should be investigated. There are many causes of inability to concentrate urine, even when dehydrated. Caution must be used when considering renal disease versus Addison's disease, since both may present with a history of polyuria/polydipsia (PU/PD), vomiting, and azotemia.

URINE DIPSTICK READINGS

Dipsticks must be stored in their tightly capped bottle, away from light and air, and in-date. When used on either whole urine or supernatant, refrigerated urine should be allowed to reach room temperature, and each color square should be checked at the appropriate time listed on the bottle, under regular office (eg, fluorescent) lighting (not daylight). Some people have difficulty perceiving the subjective color changes; there are instruments (eg, Clinitek analyzers) that can report the dipstick chemical intensity more objectively.

In general, dilute urine may give false-negative (FN) results and high specific gravity or pigmented urine may give high or false-positive (FP) results. See Table 1 below for more FN and FP dipstick findings. Disinfectants with bleach or oxidizing agents may influence a number of squares. Some dipsticks have a square for USG, but it is not as accurate as a refractometer reading.

The dipstick for pH tests over the range of pH 5 to 9. Most carnivores eating a diet of meat protein will have fasting acidic urine. Due to post-prandial alkaline tide, the pH rises after eating in the blood and urine, even in carnivores. Dogs and cats eating a diet based on vegetable protein may have alkaline urine even when fasting. When an animal comes into the veterinarian's office, especially when excited during the trip or waiting room experience, hyperventilation will tend to cause respiratory alkalosis and urine pH may rise. Bacterial infection producing urease (*Proteus, Pseudomonas,* etc, which convert urea to ammonia) and old urine samples left out too long on the counter may cause urine pH to rise. *E. coli* infections may lower pH.

The protein dipstick square is not as sensitive or reliable as the ERD (HESKA) or MA tests. Alkaline urine tends to cause a falsely high reading on the protein dipstick square. Glucose in the urine does not necessarily mean the animal is diabetic. Blood glucose must be determined, since animals may have tubular defects due to UTI, necrosis, toxins, Fanconi syndrome, or primary glycosuria.

The square for blood picks up hemoglobin and myoglobin as well as intact RBCs. Speckling indicates a few RBCs. For diffuse color change, an examination of the gross urine, urinary supernatant, sediment, as well as serum color is helpful for complete interpretation. Myoglobinuria is pigmented, but myoglobinemia is not.

Bilirubinuria is conjugated (water soluble) bilirubin, and may be seen in normal dogs as well as dogs with hemolysis or liver problems. Bilirubinuria in cats is always abnormal and can be an early warning of problems even before hyperbilirubinemia is noted. The ketone square picks up acetoacetic acid but not acetone or beta-hydroxybutyric acid. The urobilinogen square is not that useful a tool in veterinary medicine.

Don't ignore a positive nitrite square. It may indicate a urinary tract infection with bacteria that convert nitrate (from the diet) to nitrite. This conversion requires urine to be retained in the bladder for at least 4 hours.

The leukesterase square is helpful when positive, but FN results in one study occurred in about 20% of cases with an active urine sediment. Always do a urine microscopic sediment exam as part of the urinalysis.

URINE SEDIMENT

Cells, crystals, casts, bacteria, sperm, parasites, neoplastic cells, etc. may be seen in the microscopic sediment examination. Some of these are normally present and should not be over-interpreted. Struvite crystals can be seen in normal urine samples, especially as the urine pH rises (see above for reasons for alkaline pH) or when the sediment droplet being examined begins to evaporate under the microscope's lamp. High pH and struvite crystalluria should not be treated as a problem in and of themselves. Oxalate and urate crystals may be seen in acidic or neutral urine in normal animals. Cystine crystalluria is abnormal, however.

Occult UTI may be missed in dogs with Cushing's, on exogenous steroids, or with diabetes, since WBCs may not marginate or become present in the urine sample. In these cases, urine culture needs to be done to rule out urinary infection.

Table 1. False Negative and False Positive Urinary Test Results

	USG	Prot	Glu	Blood	Bili	Ket	Uro	Nitr	Leuk

CHEMISTRY RATIOS FOR THE CLINICAL DETECTIVE

Meryl P. Littman, VMD, DACVIM
School of Veterinary Medicine
University of Pennsylvania, Philadelphia, PA

Sometimes interpretation of a value on your clinical chemistry panel is made more meaningful when it is compared with other values. Certain variables may have particular relationships, either in the same direction with, or possibly diverging from, other parameters. Realizing these associations helps the astute clinical detective pick up warning flags which may be otherwise vague or easily missed. For instance, if an animal is dehydrated, it may have a pattern of changes, with values of Na^+, K^+, Cl^-, serum protein, and osmolarity above the normal range. If the animal also has pre-renal azotemia, the BUN and serum creatinine are also increased. If such an animal has a normal value for one of these parameters, for instance an unexpectedly normal value for K^+, and especially if the K^+ value is in the middle or lower end of the normal range, such a value is inconsistent with the entire picture, and the observant clinician would worry that the animal is actually whole body K^+ depleted and will likely need K^+ supplementation and monitoring, especially as intravenous fluids are given and the animal is rehydrated. Likewise, if an animal is dehydrated and has a serum albumin in the middle or lower end of the normal range, we may anticipate needs, that is, the possibility that with intravenous crystalloid therapy, the serum albumin may drop, the animal may be at risk for effusions or edema, and so we may want to prepare to monitor the animal for the potential need of colloid therapy, and we will be judicious in the quantity and rate of crystalloid therapy given. Thus, the clinician is at all times looking at the whole picture when presented with clinical data, including chemistry values, and looking at relationships and not just the numbers that are flagged with a star or an "H" or "L" for "high" and "low".

Laboratory values should be interpreted together, not as single events. What follows are some examples of the ratios that you may find helpful as a "clinical detective."

PCV/TS (PACKED CELL VOLUME/TOTAL SOLIDS)

This pair is really not a ratio, but it is a duo that is easily measured and recorded together, and is perhaps the earliest of blood test variables that the student learns to interpret together as a pair. These parameters are quickly assessed in emergency cases, and always important in any database. The PCV represents the bulk of the cellular components of the blood and is generally comparable to the hematocrit, red blood cell count, or the hemoglobin value. The TS is roughly comparable to the total protein of the plasma (although about 1 unit higher, since total protein is a subset of TS). These two variables (PCV/TS) may go up or down together, or they may diverge apart, giving important information in any situation and in any direction.

If the PCV and TS are both normal, you might think all is well. That is unless of course the animal is dehydrated, in which case perhaps rehydration will unmask anemia and hypoproteinemia. If both PCV and TS are elevated, the most common interpretation is that the volume of crystalloid in the blood is decreased (as in dehydration). If PCV and TS are both decreased, perhaps there is increased crystalloid in the blood volume compared with the blood constituents, possibly due to loss of both cells and protein after hemorrhage (blood loss), or in the case of aggressive overhydration (iatrogenic) with crystalloid therapy, or very rarely, the syndrome of inappropriate ADH secretion, which causes the animal to retain free water. The relationship may be further out of kilter as in these examples:

PCV normal with high TS:

1. The patient may be dehydrated and when rehydrated, anemia will be evident
2. The patient may have hyperglobulinemia (or less likely, hyperalbuminemia)

PCV high with normal TS:

1. The patient may have polycythemia (primary or secondary)
2. The patient may be dehydrated and when rehydrated, hypoproteinemia will be evident

NA$^+$/K$^+$ (SODIUM/POTASSIUM)

Look at the extremes of the normal ranges for these electrolytes in your lab, and see what the ratio is if you divide the lowest normal Na^+ by the highest normal K^+, and if you divide the highest normal Na^+ by the lowest normal K^+. For many labs, the normal ratio of serum Na^+/K^+ is 28–35. You can see that just by changing one variable out of the normal range a little bit, you can get an abnormal ratio which shouldn't be ignored. In the face of dehydration, both values generally increase together. Often in gastrointestinal (GI) or renal disease, with loss of both electrolytes, they go down together, and the ratio stays normal (although it is important to treat for these abnormalities). When the Na^+/K^+ ratio is low, we think of possible Addison's disease and plan to begin an ACTH stimulation test as soon as possible. Of course there are other reasons for a low ratio, such as whipworms, renal failure, GI (especially colonic) disease, effusive disease, or falsely high potassium due to thrombocytosis or K^+ EDTA contamination. If the Na^+/K^+ ratio is high, we consider steroidal causes, especially Na^+ retention due to hyperaldosteronism, or abnormal gastrointestinal or renal loss of K^+ in the face of dehydration causing elevated Na^+.

BUN/CREATININE (BLOOD UREA NITROGEN/CREATININE)

Normally this ratio is roughly 20 (range 9–33). If you look at your normals for BUN and creatinine from your lab, and take the extremes of each to see what the range might be if the two were completely divergent, the range is too broad (3–43) to seem helpful, so I use 10–30 as a rough guideline for normal.

Both of these substances are present in the glomerular filtrate and excreted by the kidneys. When the animal is dehydrated or overhydrated, they generally move in the same direction and the ratio stays about the same. Exceptions include sudden acute renal azotemia, prerenal azotemia, or rupture in the urinary tract, when BUN may increase due to pre-renal factors more than the slower rise of creatinine. It is helpful to recall where these substances come from. Protein in the diet is digested by proteases in the gut and amino acids deaminated by bacterial flora producing ammonia. Ammonia then travels from the GI tract via the portal venous blood to the liver where the urea cycle converts it to urea (NH_2-NH_2, called blood urea nitrogen on our panel). BUN also comes from protein catabolism in the body. If the liver is diseased such that there is congenital or acquired shunting of portal venous blood away from the liver, or if there is a rare urea cycle enzyme deficiency, then urea will not be synthesized and BUN will be lower than expected, relative to the serum creatinine. If there is a high protein diet, urea would tend to be high. Creatinine on the other hand comes from muscle with a daily constant turnover. If the animal is muscle wasted, or a very young puppy without much muscle as yet, then there isn't as much creatinine circulating to excrete. On the other hand, a very muscle-bound athlete in an anabolic state may have a higher creatinine turnover. Let's see how the BUN/creatinine ratio may be impacted in these examples:

Low BUN/creatinine ratio (eg, <10):

1. liver disease
2. animal is eating a low protein diet
3. animal is very well-muscled, with increased muscle mass (anabolic)

High BUN/creatinine ratio (eg, >35):

1. animal is eating a high protein diet
2. GI bleeding, which is as if the animal is eating blood, which is a high protein meal
3. catabolic disease, increased protein breakdown in the body
4. low muscle mass, causing the creatinine to be lower than expected compared with the BUN
5. hypovolemia/pre-renal azotemia (which also predisposes to GI ulceration)

A/G RATIO (ALBUMIN/GLOBULIN)

Normally this ratio is roughly 1. Albumin is only made by the liver. Globulins are made in the liver as well as by immunocytes. Albumin is a much smaller molecule (MW 60,000) compared with large globulin molecules, so that more albumin than globulin would be lost through diseased glomeruli (eg, protein-losing nephropathy, PLN) or vasculitis, where the pore size for leakage is small, whereas both albumin and globulin are lost from diseased intestine, with a larger leakage pore size (eg, in protein-losing enteropathy, PLE). Disease of the GI tract would lose whole plasma (albumin and globulins) and possibly whole blood including rbc's (GI ulceration). By looking at the total protein as well as the relationship of albumin to globulin, we can start to sort out PLE, PLN, liver disease, etc. Here are some examples:

- Total protein is high with normal A/G ratio: dehydration
- Total protein is low with normal A/G ratio:
  - loss of albumin and globulin together due to hemorrhage, plasma protein loss (PLE), burns, or exudative effusions
  - overhydration, dilution
- Total protein is low or normal with low A/G ratio: low albumin due to liver disease or PLN
- Total protein is low or normal with high A/G ratio: low globulin due to immunodeficiency
- Total protein is high or normal with low A/G ratio: high globulin state (gammopathy)
- Total protein is high or normal with high A/G ratio: high albumin due to hepatoma (rare)

Other parameters which will help in the diagnosis of PLE and PLN are the serum cholesterol and the PCV. Dogs with PLN tend to have high cholesterol, whereas dogs with PLE tend to have low cholesterol. Dogs with both PLE and PLN may have normal cholesterol. Dogs with GI bleeding may first appear as those with PLE because of their low albumin and globulin levels, but check the PCV, since anemia with panhypoproteinemia suggests GI hemorrhage. Signs of iron deficiency on the CBC (microcytosis – low MCV, hypochromia – low MCHC) may help support hemorrhage as a cause of anemia. Dogs with liver disease may be complicated in that they may have low PCV due to chronic disease or GI hemorrhage, low albumin due to decreased production, panhypoproteinemia due to GI hemorrhage, and cholesterol may be low, normal, or high with liver disease. Other parameters, such as ALT, alkaline phosphatase, and bilirubin may then be helpful. Beyond the biochemical profile, other tests include urine testing for proteinuria, abdominal imaging, serum bile acids, fecal alpha-1-proteinase inhibitor, endoscopy/biopsy, etc. may be necessary to help differentiate PLE, PLN, liver disease, GI ulceration, etc.

ALK PHOS/ALT (SERUM ALKALINE PHOSPHATASE/SERUM ALANINE AMINOTRANSFERASE)

In general, the serum alkaline phosphatase and serum ALT can be checked to see if they are traveling together or alone. In dogs, if the Alk Phos is elevated alone or is much higher than the ALT rise, we suspect pituitary hyperadrenocorticism, adrenal tumor, or exogenous steroid administration (iatrogenic). In puppies, we usually see elevated Alk Phos by itself, due to the bone isoenzyme of Alk Phos from osteoblastic activity during growth. Later in life, bone cancer with osteoblastic activity may also cause Alk Phos to rise independently of ALT. In liver disease, the ALT and Alk Phos both go up together and the Alk Phos is generally not much higher than the ALT unless there is cholestasis without leakage (as seen with cirrhosis and few hepatocytes left to leak ALT, or infiltrative diseases such as lymphoma). In cholestatic situations, the serum and urine bilirubin are probably elevated. Bilirubin is generally normal in steroid-induced hepatopathy. Sometimes it is helpful to submit blood for Alk Phos isoenzyme analysis, to quantitate hepatic vs. steroid-induced vs. bone isoenzymes of Alk Phos.

ALT/AST (SERUM ALANINE AMINOTRANSFERASE/SERUM ASPARTATE AMINOTRANSFERASE)

These two transaminases are leakage enzymes and the values usually rise at around the same rate when due to liver disease. Since AST is not liver specific, if the AST rises without a similar rise in ALT, consider muscle damage or hemolysis. A CK (creatine kinase) assay will help check for muscle damage.

CA/PHOS or CA/P (CALCIUM/PHOSPHORUS)

These two variables often go separate ways, due to the law of mass action. When the calcium goes down, the phosphorus usually goes up, and vice versa. Consider these situations:

Low Ca/P ratio with low Ca and high Phos:
1. Hypocalcemia due to renal hyperparathyroidism
2. Nutritional hyperparathyroidism
3. Hypoparathyroidism

High Ca/P ratio with high Ca and low Phos:
1. Hypercalcemia due to lymphoma
2. Primary hyperparathyroidism

Normal Ca/P ratio with high Ca and high Phos:
1. Hypervitaminosis D
2. Adenomatous renal hyperparathyroidism with renal failure

NA/CI (SODIUM/CHLORIDE)

These electrolytes usually go up or down together, as in dehydration or GI losses. But if they are divergent, this clue may help you make your diagnosis! Consider these situations:

Na^+ is high, Cl^- is low:
1. Dehydration with possible GI loss of HCl (vomiting), as in metabolic alkalosis
2. Alkalosis

Na^+ is normal, Cl^- is high:
1. KBr administration (false high Cl^-)
2. Hyperchloremic metabolic acidosis as in renal tubular acidosis with loss of bicarbonate (check TCO2, blood gases, kidney parameters)
3. Acidosis

Other ratios of interest include the urinary ratios of protein/creatinine, cortisol/creatinine, bile acids/ creatinine, etc.

PROTEINURIA: DON'T MISS IT

Meryl P. Littman, VMD, Diplomate ACVIM
School of Veterinary Medicine
University of Pennsylvania, Philadelphia, PA

Proteinuria is relatively easy to check for and is one of those potential "silent killer" markers that can be associated with simmering damage which might otherwise go unnoticed by even the most observant owner. If proteinuria continues unrecognized, a variety of clinical signs could occur down the road, including severe and dramatic signs, with less chance of reversal or stabilization and more risk of morbidity and mortality.

Checking for proteinuria should be part of the annual wellness examination in all dogs and cats. Here we briefly answer questions clinicians want answered: Why should we bother checking for proteinuria, how often should we check for it, and which test should we use?

WHY SHOULD WE BOTHER CHECKING FOR PROTEINURIA?

Large amounts of protein in the urine which are associated with glomerular disease can lead to the nephrotic syndrome which can cause serious sequellae including death, even before azotemia and signs of renal failure occur. Significant proteinuria may lead to hypoalbuminemia and loss of antithrombin III, with the attendant risk for effusions, edema, and thromboembolic events. Even small amounts of protein leaking into the glomerular filtrate may cause tubular damage further down the nephron, and eventually renal function may decline due to decreased renal reserve, leading to renal failure. Hypertension (another silent killer) can be either a cause or effect of renal disease, especially glomerular disease. If we detect proteinuria, it is a reminder to check the blood pressure measurement and potentially avoid target organ damage from hypertension, including changes to the eye (blindness due to retinal hemorrhage or detachment), cardiovascular system (hypertrophic cardiomyopathy, arteriosclerosis, epistaxis), kidney (nephrosclerosis), and/or cerebrovascular system (cerebrovascular accidents or "strokes"). Other underlying diseases causing proteinuria, such as lupus, amyloidosis, or infectious/inflammatory, neoplastic, or genetic diseases triggering immune-mediated glomerulonephritis or glomerulopathy, may be first recognized by detection of proteinuria, a warning flag to look further. And vice versa: animals with infections, cancer, or immune-mediated disease affecting other organs (eg, polyarthropathy, hemolytic anemia, thrombocytopenia, pemphigus, myositis, myasthenia gravis, etc) should be closely monitored for the development of proteinuria. Screening for occult proteinuria in breeding stock may help future generations avoid familial protein-losing nephropathy; screening non-breeding individuals of such predisposed breeds will help spot those that may benefit from early therapeutic intervention.

Hypertension

Systemic hypertension (from any cause) increases glomerular filtration pressure and may cause proteinuria. Currently in veterinary medicine, measuring blood pressure is not done as routinely or as easily as is screening for proteinuria. Whenever proteinuria is found, a blood pressure measurement and retinal examination should be done. If proteinuria screening were not included in the wellness exam, occult target organ damage from hypertension may be missed as well, and possibly progress unchecked until gross clinical signs of blindness, epistaxis, or neurologic signs could occur.

Some causes of systemic hypertension include renal disease (especially glomerular disease), adrenal disease (Cushing's, hyperaldosteronism, pheochromocytoma), and thyroid disease (hyperthyroidism in cats and hypothyroidism in dogs). Examples of iatrogenic hypertension include exogenous steroids, high dietary salt intake in the rare salt sensitive individual, and phenylpropanolamine (PPA) treatment for canine urinary incontinence. Blood pressure measurement and screening for proteinuria should be monitored in cases so treated.

Infectious Diseases May Trigger Immune-Mediated Glomerulonephritis

Infectious diseases may cause glomerulonephritis and proteinuria due to immune-mediated complex deposition in glomeruli. Glomerulonephritis may be caused by acute infections, for instance with Rocky Mountain Spotted Fever or adenovirus-1 (infectious canine hepatitis), or chronic immune stimulation and glomerular immune-complex deposition may occur in carriers of many other infections such as anaplasmosis, babesiosis, bacterial infections, bartonellosis, borreliosis (Lyme disease), brucellosis, dirofilariasis (heartworm), ehrlichiosis, FeLV/FIV, fungal infections, hepatozoonosis, leishmaniasis, mycoplasmosis, and others. Some of these diseases may also cause vasculitis, polyarthropathy (synovitis), meningitis, uveitis, endocarditis, and/or bone marrow damage or immune-mediated cytopenias, such as thrombocytopenia, anemia, and/or neutropenia. If an infectious disease is causing proteinuria and is allowed to progress, more damage to the kidney will be ongoing, leading potentially to nephrotic syndrome, hypertensive target organ damage, and/or renal failure. Animals found to have infectious disease should be checked for proteinuria, and vice versa (animals with proteinuria should be checked for infectious diseases in their area). The commonly used in-house screening test, SNAP-4Dx (IDEXX) for heartworm antigen and antibodies against *Borrelia* (Lyme), *Anaplasma*, and *Ehrlichia* may identify seropositive animals. It is very rewarding to be able to detect and treat occult proteinuria in seemingly normal asymptomatic animals at a time when early intervention may make a real impact.

Genetic Predisposition for Proteinuria in Some Breeds

In breeds with familial glomerulopathy or amyloidosis, if genetic marker tests are as yet unavailable, screening for proteinuria before the animal is bred (several times a year), or annually for non-breeding pets, is advocated by conscientious breed clubs. A cut-off for normal urine protein/creatinine ratio of less than 0.4 may be used, and higher values investigated as to cause (eg, rule out urinary tract infection, calculi, etc). Examples of breeds predisposed to proteinuria include Bernese Mountain Dog, Bull Mastiff, Bull Terrier, English Cocker Spaniel, Samoyed, Soft Coated Wheaten Terrier, Shar pei, and others. Breeds that are predisposed to Lyme nephritis may also be monitored more closely, including Labrador and Golden retrievers, and Shetland Sheepdogs.

HOW OFTEN SHOULD WE CHECK FOR PROTEINURIA?

The ACVIM Consensus Statement on Proteinuria[1] recommended that dogs and cats be checked annually, as part of their wellness exam. Urine testing is also an important part of the database for sick patients. If a patient is proteinuric, guidelines (see Table 1) are given as to monitoring (for magnitude, persistence, and trend), investigation (for localization and diagnostic workup for cause), and therapeutic intervention (specific, supportive, and symptomatic). Mild proteinuria should be monitored over time to study progression or stability, and to notice any trend. Moderate to severe proteinuria should be monitored even more closely as well as investigated with other testing, for instance, urine protein/creatinine ratio, blood pressure measurements, CBC, biochemical profile, urine culture/sensitivity, chest radiographs, abdominal ultrasound, serologic tests for infectious diseases in the area, and possible renal biopsy. These patients should also have intervention, including an angiotensin-converting enzyme (ACE) inhibitor, antithrombotic low dose of baby aspirin (if hypoalbuminemic), amlodipine (if still hypertensive despite ACE inhibitor therapy), omega-3 fatty acid supplementation, diet modifications, and possibly, anti-emetics, antacids, phosphate binders, immunosuppressants, colloid or crystalloid supportive therapy, etc.

All dogs which are seropositive for antibodies against *Ehrlichia*, *Anaplasma*, or Lyme should be checked for proteinuria. Whether or not they are treated with doxycycline (and the current consensus is that they do not all need to be treated), when should they be rechecked for proteinuria? Since the carrier state may not always be cleared even if they are treated, I recommend rechecking for proteinuria two to three times/year (not just annually) in these dogs.

WHICH TEST SHOULD WE USE?

Searching for protein in the urine by dipstick can give false negative or false positive results. The dipstick square showing shades of green can be misinterpreted because of ambient lighting conditions, outdated sticks, dipstick bottles left open, etc. Almost 10% of men have some form of colorblindness and may find reading the dipstick problematic. False positives may be due to alkaline urine (due to respiratory alkalosis in excited, hyperventilating dogs; post-prandial sampling; or an old urine sample left out on the counter too long), pigmenturia (which turns all dipstick squares darker), or a highly concentrated urine. False negatives can be seen with dilute urine and old sticks.

Microalbuminuria (MA) tests are now available and are more sensitive and specific than the urine dipstick for protein. The in-house test, E.R.D. (HESKA) can be used as a routine initial screening tool, or a microalbuminuria assay may be included with the full urinalysis by an outside reference laboratory (eg, Antech Diagnostic Laboratories). E.R.D. results are read as negative, low, medium, high, or very highly abnormal (in urine diluted to a 1.010 specific gravity), or MA may be quantitated per urine volume in mg/dL. Monitoring for persistence and following the trend is important for low or medium results. For high or very high E.R.D. results, I recommend switching over to the quantitative MA or urine protein/creatinine ratio (Up/c).

Urine protein levels are not seriously impacted by the presence of microscopic amounts of blood in the sample (commonly occurring with cystocentesis samples), however, urine samples which are grossly bloody will have increased protein levels which interfere with diagnostic interpretations.

The source of proteinuria needs to be localized (pre-renal, renal, post-renal). Infection, inflammation (calculi), or neoplasia of the lower tract (bladder, prostate, urethra, prepuce/vagina) is common and needs to be ruled out so that proteinuria is not misinterpreted as a glomerular leak. Examination of urinary sediment for evidence of inflammatory cells is important, since the urine dipstick square for leukesterase often gives false negative results.

Table 1 gives guidelines recommended by the ACVIM Consensus on Proteinuria using the Up/c quantitation method for proteinuria.

Table 1. Guidelines Recommended by the ACVIM Consensus on Proteinuria using the Up/c Quantitation Method for Proteinuria

	Non-Azotemic Dogs and Cats	**Azotemic Dogs**	**Azotemic Cats**
Monitor	Up/c ≥ 0.5	Up/c < 0.5	Up/c < 0.4
Investigate	Up/c ≥ 1.0	Up/c < 0.5	Up/c < 0.4
Intervene	Up/c ≥ 2.0**	Up/c ≥ 0.5	Up/c ≥ 0.4

**Some clinicians use a lower cut-off for intervention, eg, starting to use an ACE inhibitor when Up/c is ≥ 1.0.

PAIN MANAGEMENT IN ORAL SURGERY

Brett Beckman, DVM, FAVD, Diplomate AVDC & AAPM
Affiliated Veterinary Specialists, Orlando, FL
Florida Veterinary Dentistry and Oral Surgery,
Punta Gorda, FL

The utilization of regional nerve blocks for oral surgery in dogs and cats is synonymous with quality patient care. This article details techniques that can be incorporated into the companion animal hospital dentistry service to maximize safety, care and comfort for patients undergoing oral surgical procedures. This discussion also suggests adopting less misleading names for the regional nerve blocks, relying on simple anatomical regions blocked rather than the traditional confusing nomenclature.

Detailed descriptions of regional and local nerve blocks commonly utilized to provide analgesia for oral surgery in veterinary patients have appeared in numerous publications. Complete analgesia to the targeted tissue and a reduction in the concentration of the inhalant anesthetic are two significant benefits of proper administration of local agents. Hypotension, bradycardia, and hypoventilation are complications that can be minimized by the use of local and regional blocks for oral surgery. Local blocks eliminate the perception of pain making surgical anesthetic depths unnecessary.

AGENTS

This author commonly uses lidocaine[a] and bupivicaine[b] combined in the same syringe for regional oral nerve blocks. Lidocaine is not desirable as a sole agent due to its limited effect post administration (1–2 hours). Bupivicaine requires administration much earlier in the anesthetic event than lidocaine in order to be effective prior to surgical tissue manipulation. These limitations can be minimized or eliminated by using them in combination. The quick onset of lidocaine coupled with bupivicaine's extended duration of effect (up to 8 hours[5]) make them a good choice for combined use in regional nerve blocks. The agents may be used with or without epinephrine.

Although rare, complications are possible with inadvertent systemic administration or systemic uptake of locally delivered local anesthetic agents. Central nervous system excitement including seizures followed by depression, apnea, severe cardiovascular compromise, dysrhythmias and hypotension are all possible. Direct toxicity to skeletal muscle and anaphylactic reactions are possible with local administration. The author has never experienced any of these complications at the doses recommended in this article.

A maximum dose of 1.0 mg/kg of each agent in combination in the same syringe is recommended. Care should be exercised, especially in smaller patients and cats, so that maximum doses are not exceeded. The ratio of lidocaine:bupivicaine is 1:4 when using concentrations of 2% and 0.5 %, respectively. The total volume used depends upon the size of the patient and the number of sites that require analgesia. The maximum number of sites would be four if the patient requires surgical manipulation in all four quadrants. Table 1 shows recommended infusion volumes per site based upon patient size. Please note that these volumes represent both agents mixed together. Table 2 shows a sample calculation for a 40-kg dog.

Table 1. Recommended infusion volumes per site of lidocaine:bupivicaine

	Weight	Infusion Volume
Feline/Small dog	Up to 6 kg	0.1–0.3 mL
Medium dog	6–25 kg	0.3–0.6 mL
Large dog	26–40kg	0.8–1.2 mL
Extra large dog	over 41 kg	1.4–1.6 mL

Table 2. Sample calculation for a regional nerve block for oral surgery for a 40 kg dog

Patient Size = 40 kg
Regional Blocks desired = 3
Lidocaine 2% = 20.0 mg/mL
Bupivicaine 0.5% = 5 mg/mL

Calculation:
1.0 mg/kg x 40.0 kg = 40 mg total patient dose of each

Calculation:
Volume infused = total patient dose divided by the concentration of the agent
Volume infused for lidocaine 2% = 40 mg divided by 20 mg/mL = 2.0 mL
Volume infused for bupivicaine 0.5% = 40 mg divided by 0.5 mg/mL = 8.0 mL

The total dose of both agents combined for administration in the same syringe is 10 mL. Therefore, 3.33 mL could be used for each site. However, the recommended volume to be infused from Table 1 for this size patient is only 0.8–1.2 mL, so you would not need to draw up the total volume.

Calculation:
3 sites at 1.2 mL per site = 3.6 mL
3.6 x 0.25 = 0.9 mL lidocaine
3.6 x 0.75 = 2.7 mL bupivicaine

Physiologic parameters will determine if the block is effective. If blood pressure, heart rate, and respiration rate increase with surgical manipulation the block either was not correctly placed or hasn't had the proper amount of time for onset (5 minutes). If enough time has elapsed to be comfortable that onset is not an issue the block may be repeated as long as the maximum total dose is not exceeded. It should be noted that the low pH of inflamed tissue will render local anesthetics less effective.

OPIATES

Based upon human research the use of local analgesics and opiates in combination provides extended duration of action. The addition of morphine[c] or buprenorphine[d] to a regional brachial plexus block for limb amputation demonstrated close to a twofold increase in duration of effect over patients receiving only bupivicaine in one study. A similar model was used in another study where researchers demonstrated that the addition of buprenorphine to the regional block provided significant increases in duration compared to giving the buprenorphine intramuscularly.[7]

The author currently ulitizes opiates in the lidocaine:bupivicaine mixture for procedures where increased duration of effect is desirable. Patients that are particularly difficult to medicate, either in the hospital or at home, may benefit from this combination. Also patients in which chronic pain states exist, as seen in canine or feline stomatitis, may make postoperative pain management challenging. Morphine may be used as a portion of the premedication protocol at 0.5 mg/kg IM 20 minutes prior to induction. One fourth of that same volume is added to the local mixture per site to be blocked. Hydromorphone[e] is administered at 0.1 mg/kg as a portion of the premedication protocol. One fourth of that same volume is also added to the local mixture per site to be blocked. Buprenorphine may also be used as a premedication at 0.015 mg/kg following the same volume recommendations for local infiltration as with the examples above. Morphine and hydromporphone are pure mu agonists and are preferred for management of severe pain. Buprenorphine is a partial mu agonist and is a good choice for mild to moderate pain. All three agents may be used in either species; however, pure mu agonists, in particular hydromorphone, are known to cause hyperthermia in cats. If pure mu agonists are used either locally or systemically in cats, temperature should be monitored during and up to 5 hours post procedure.[8]

EQUIPMENT

None of the regional nerve blocks for oral surgery in dogs and cats need any special equipment to employ. A tuberculin syringe with a 5/8-inch 25-gauge needle is used for patients 4 kg or less. Three or six mL syringes with 22- to 25-gauge ¾-inch needles are used for patients over 4 kg depending upon the volume to be infused. The correct dose of the desired agents is drawn. The needle is advanced to the desired location. Aspiration is performed to ensure that the needle is not in a vessel and the agent is dispersed. If one encounters a vessel the needle is redirected and aspiration repeated. Once extravascular placement is confirmed the agent is administered. Be careful not to advance the needle during injection to avoid inadvertent vessel penetration.

REGIONAL NERVE BLOCKS

Four regional nerve blocks are commonly utilized to provide local analgesia to the different regions of the oral cavity. These blocks have confusing nomenclature in that the block may refer to the region blocked or the actual nerve that is blocked. This discussion suggests simplification and clarification of nomenclature to describe the region affected rather than the nerve blocked.

Two blocks exist for the maxilla. The rostral maxillary infiltrates the infraorbital nerve prior to exiting the infraorbital canal. The caudal maxillary anesthetizes both the infraorbital nerve and pterygopalatine nerve caudal to the second maxillary molar. The regional mandibular blocks include two blocks as well. The caudal mandibular infiltrates the inferior alveolar nerve on the lingual aspect of the mandible prior to its entry into the mandibular canal. The rostral mandibular anesthetizes the inferior alveolar nerve within the mandibular canal via the mental foramen.

The regional nerve blocks for oral surgery are similar for the dog and the cat. Some anatomical differences do exist, however. Variations in the approach to cats will be described following the discussion of these four regional blocks for dogs. The proposed new names are followed by the often confusing traditional names of these blocks in parentheses.

ROSTRAL MAXILLARY (INFRAORBITAL) REGIONALBLOCK

The rostral maxillary block provides infiltration of the lidocaine/bupivicaine combination adjacent to the infraorbital nerve and the rostral maxillary alveolar nerve within the infraorbital canal. The latter leaves the inferior alveolar nerve within the canal to enter the incisivomaxillary foramen to innervate the canine and incisor teeth. In addition, the first three premolar teeth as well as the maxillary bone and surrounding soft tissue are affected. To perform this block, retract the lip dorsally. Palpate the infraorbital neurovascular bundle beneath the vestibular mucosa. This is a large cylindrical band that exits the infraorbital canal dorsal to the distal root of the maxillary third premolar. The thumb of one hand can be used to retract the bundle dorsally. With the opposite hand the needle is advanced close to the maxillary bone ventral to the retracted bundle in a rostral to caudal direction to a point just inside the canal. The needle should pass without engaging bone. If bone is encountered the needle is withdrawn slightly and redirected until it passes resistance free into the canal. Proper insertion can be confirmed by gentle lateral movement of the syringe whereby the needle will meet resistance with the lateral canal wall.

CAUDAL MAXILLARY (MAXILLARY) REGIONAL BLOCK

The caudal maxillary block allows infiltration of the local anesthetic combination adjacent to the infraorbital nerve and the pterygopalatine nerve caudal to the second maxillary molar. These nerves are branches of the maxillary nerve that supply sensory innervation to the maxilla. In addition to the structures affected by the infraorbital block it will anesthetize the caudal cheek teeth and associated bone and soft tissue. The soft palatal mucosa and hard palatal mucosa and bone will also be affected by this block. To perform this block the mouth is opened wide and the lips retracted caudally at the lateral commissure. The needle is directed in a dorsal direction immediately behind the central portion of the maxillary second molar tooth. Advancement of the needle need not be more than 2–4 mms depending upon patient size.

ROSTRAL MANDIBULAR (MENTAL) REGIONAL BLOCK

The rostral mandibular block infiltrates the rostral extent of the inferior alveolar nerve just before it exits the middle mental foramen. The structures anesthetized include the incisors, the canine and the first three premolars. The adjacent bone and soft tissue are also affected. The middle mental foramen is located about one third of the distance from the ventral border to the dorsal border of the mandible at the level of the mesial root of the second premolar. The landmark for infiltration is the mandibular labial frenulum. The frenulum is retracted ventrally. The needle is inserted at the rostral aspect of the frenulum and advanced along the mandibular bone to just enter the canal. If bone is encountered the needle should be backed out and redirected until the needle passes freely into the foramen. Placement can be confirmed by moving the syringe laterally to encounter the lateral aspect of the canal. The patient's jaw, rather than the alveolar mucosa, will move slightly if the needle is within the canal.

CAUDAL MANDIBULAR (INFERIOR ALVEOLAR) REGIONAL BLOCK

The caudal mandibular block is performed by infiltrating the inferior alveolar nerve prior to its entry into the mandibular foramen on the lingual aspect of the caudal mandibular body. The lateral canthus of the eye is the landmark for this block. An imaginary plumb line is drawn from the lateral canthus of the eye directly to the ventral mandible. The needle is inserted into the skin at the lingual aspect of the ventral mandible at this point. The needle is advanced along the bone following the imaginary plumb line to a point one third of the distance from the ventral to the dorsal mandible. The needle will now be in the vicinity of the mandibular foramen where the inferior alveolar nerve enters the mandibular canal. It is not critical to be exactly at the foramen. Radiographic dye studies indicate that the agent diffuses to encompass a large area around the point of infusion. This technique blocks all of the teeth of the mandible on the side of infiltration as well as the adjacent bone and soft tissue.

Although very uncommon, patients receiving an caudal mandibular nerve block have been known to traumatize their tongues by mastication in the postoperative period. Observation and proper recovery assistance during this period will eliminate this complication. Staff members monitoring the recovering patient should ensure visual confirmation that the tongue is not trapped between the carnassial teeth if the patient is recovered in lateral recumbency. Maintaining the patient in sternal recumbency precludes the tongue deviation expected when a patient is laterally recumbent.

FELINE ANATOMICAL DIFFERENCES

Anatomical differences between species require slight variations in technique when considering nerve blocks in cats. When performing the rostral maxillary (infraorbital) nerve block in cats the approach is the same as described in the dog; however, the infraorbital foramen is relatively more dorsal in the cat. Therefore needle should be inserted more dorsally and then advanced in a rostral to caudal direction into the infraorbital foramen. As in the dog, the needle should not engage bone and should pass directly into the foramen.

The infraorbital canal in cats is also much shorter and the foramen relatively larger than that found in the dog. Because the canal is only a few millimeters long administration of the agent into the canal also places it adjacent to the infraorbital and pterygopalatine nerves. This results in creating the same effect as the caudal maxillary nerve block in dogs. In this discussion it is suggested that the single nerve block for the cat maxilla be termed the *maxillary nerve block* since it is performed as is the rostral maxillary block in dogs but blocks the same region as the caudal maxillary block.

Cats have no mandibular first and second premolars; therefore, the middle mental foramen in the cat is located midway between the mandibular canine and third premolar. Only in very small cats is this foramen not accessible to needle placement for administration of the rostral mandibular block. If one encounters difficulty the caudal mandibular block may be used as an alternative.

CONCLUSION

Regional nerve blocks for oral surgery are valuable tools in enhancing patient safety intraoperatively and patient comfort postoperatively. They are easy to administer and require no special equipment to perform. Their use encourages quick return to normal mastication and continuation of normal food and water intake shortly after oral procedures. Incorporation of oral regional nerve blocks into the dentistry service is paramount in providing the best in patient care. Simplification and clarification of nomenclature should be considered to eliminate confusion between descriptions of actual anatomical regions and the nerves themselves.

NONINVASIVE ORAL FRACTURE REPAIR

Brett Beckman, DVM, FAVD, Diplomate AVDC & AAPM
Affiliated Veterinary Specialists, Orlando, FL
Florida Veterinary Dentistry and Oral Surgery,
Punta Gorda, FL

Oral fracture repair in dogs and cats has traditionally taken many different forms. Pins, plates, screws, and external coaptation devices are all methods previously employed that are relatively invasive. Small dogs and cats and immature animals have very little bone volume to support the more invasive devices often resulting in failure. Noninvasive methods employing the teeth and using interdental wiring, orthodontic devices, composite and acrylic can bypass traditional invasive methods decreasing procedure time and ensuring a comfortable occlusion and rapid return to function.

PATIENT EVALUATION

Oral fractures are particularly painful. Pain management should be an immediate concern for all patients with oral fractures. Immediate assessment of patient status should take into consideration possible complications of administration of certain analgesics. For example, patients with concurrent ocular trauma and potential glaucoma should not be given morphine in that associated vomiting from this agent will result in and acute increase intraocular pressure. Opiates should be avoided or used with caution in patients with respiratory compromise due their potential for causing respiratory depression. Nonsteroidal anti-inflammatory drugs (NSAIDs) should not be used in patients with hypovolemia, dehydration, or renal compromise. The patient should be considered as a whole when choosing appropriate analgesics.

A minimum data base should include a thorough physical examination, CBC, chemistry profile, electrolytes, blood gas analysis, urinalysis, thoracic and abdominal radiography and an EKG. Total patient analysis is paramount prior to consideration for sedation and oral evaluation.

Following the evaluation of the minimum database disposition is made concerning safety for general anesthesia and gross and radiographic evaluation of the oral cavity. If the minimum data base suggests that anesthesia is contraindicated preparation is made to compensate the patient for critical issues delaying anesthesia until the appropriate time. If definitive treatment must be delayed a tape muzzle should be placed to minimize additional tissue trauma from movement unless respiratory distress or vomiting are more pressing concerns.

The oral examination under anesthesia should include careful intubation not only for inhalant administration but just as importantly for airway protection. Oral hemorrhage and vomiting are common with head trauma and could severely decompensate the patient if an airway is not immediately established upon induction. A careful thorough oral examination should include maxillary and mandibular bone palpation, visual examination for swellings and lacerations in and around the oral cavity and skull, open fractures, epistaxis, temporomandibular joint (TMJ) fractures and luxations, symphyseal fractures, tooth fractures, tooth luxations and avulsions, malocclusions and lingual trauma.

Full mouth dental radiography is indicated following a thorough oral evaluation. Detail obtained from dental radiography allows for detection of lesions not possible with conventional skull films. Oblique and ventrodorsal (VD) TMJ films are indicated if assessment indicates possible problems in this area.

MANDIBULAR FRACTURES

Fractures of the mandible are more common and often more challenging than maxillary fractures in both dogs and cats. Displacement may be significant especially if both mandibles are involved. When repairing mandibular fractures primary attention must be paid to occlusion. If the teeth are returned to proper occlusion with noninvasive techniques, fracture repair is simultaneously accomplished. A proper occlusion eliminates tooth on tooth or tooth on tissue trauma postoperatively that might compromise apposition. Occlusion cannon be assessed without extubation and bite evaluation. Therefore, it is often helpful to perform a pharyngostomy to reposition the endotracheal tube so that occlusion can be checked during and after repair.

FAVORABLE FRACTURES

Favorable fractures are mandibular fractures where the normal forces of opening and closing the mouth aid in apposition of the fracture ends. The fracture line in these cases runs from the rostroventral to the caudodorsal mandible. Normal digastricus muscle function pulls the rostral aspect of the mandible caudally when opening the mouth. Similarly the temporalis and masseter muscles act to pull the caudal mandible in a rostral direction when closing the mouth. Therefore, the both processes of opening and closing the mouth impose favorable forces to oppose fracture ends in this type of injury. These fractures are often repaired solely with the aid of an acrylic splint applied to the lingual aspect of the teeth as the jaws are brought into occlusion.

NONFAVORABLE FRACTURES

Nonfavorable fractures exist when opening and closing of the mouth provides distraction forces to the fracture ends. When a fracture line runs rostrodorsal to caudoventral the muscles of mastication instill an effect opposite that of favorable fractures. These fractures require additional stabilization with interdental wiring and acrylic stabilization. Traditional methods aimed at providing minimal invasiveness include interosseous wiring. This is seldom needed when wiring and acrylic with or without a tape muzzle are employed during healing. Suturing of soft tissue should be delayed until stabilization is achieved in case interosseous wiring is needed. If this is the case access can be achieved in part via the existing defect.

TEETH AS ANCHORS

Teeth within the fracture line should be salvaged if possible. Severe periodontal disease and/or endodontic disease that is preexisting may warrant extraction in come cases. Treatment of these teeth following fracture healing depends on the ability of the dentist to treat the tooth or the bone loss at the time of the fracture. This topic extends well beyond the scope of this manuscript. Veterinary dental texts provide extensive discussions on periodontal and endodontic therapy for teeth in general. In most cases fracture repair can be completed utilizing the techniques described here. At discharge referral can be scheduled with a veterinary dentist for follow-up care of the teeth involved in the fracture line or otherwise traumatized. It is very important that client communication with this topic is discussed. Pet owners should be notified that traumatized teeth will require follow-up visits with a specialist or qualified individual after discharge from fracture repair. Extraction or endodontic therapy is often indicated especially if the tooth or teeth in question are involved with the fracture line.

MAXILLARY FRACTURES

Maxillary fractures commonly require little in the form of rigid fixation Soft tissue apposition, tape muzzles and/or acrylic splints are all that is needed in most cases. Epistaxis is a common sequela to maxillary fractures and usually resolves shortly after surgical repair. Ventrodorsal intraoral dental radiography should be employed to check for intranasal bone fragments in cases of severe nasal or maxillary trauma with epistaxis. Removal of fragments will prevent sequestra leading to chronic bacterial rhinitis. This may be accomplished through a displaced palatal fracture site or through dorsal rhinotomy.

ORTHODONTIC DEVICES

Orthodontic massel chain and button configurations have the advantage of providing fixation but eliminating rigidity associated with splints and wires. This may be of special benefit in young patients where jaw growth is not complete to allow some flexibility to further growth. When used alone massel chain and button configurations should be used with tape muzzles and Elizabethan collars to prevent trauma and minimize jaw movement. Orthodontic devices can also be integrated into acrylic splints where additional rigidity is required. Creative application of button and chain configurations may stand alone or form the backbone of acrylic splints providing excellent rigidity eliminating the need for interdental wiring.

INTERDENTAL WIRING

Interdental wiring is a viable noninvasive technique that can be used with or without stabilization with acrylic. It involves placement of 24- to 26-gauge wire between teeth on either side of the fracture line. Wire is generally placed ventral to the cervical bulge at the mesial and distal aspects of the teeth. Anatomical variations may dictate that the wire be passed through the gingiva to establish purchase. Notching of the tooth with a small round carbide dental bur or the utilization of composite bonding to secure the wire to the tooth are also possible. Wiring techniques are described extensively in veterinary dental texts. The Stout multiple loop technique provides incorporation of two or more teeth on either side of the fracture line. The Ivy loop technique is similar but incorporates only one tooth on either side of the fracture line. For mandibular fractures the loops are tied on the lingual aspect to eliminate problems with occlusion from the maxillary teeth and to act to reinforce purchase of the acrylic. More extensive fractures may require additional techniques. The Risdon's wiring technique may be used in these instances.

ACRYLICS AND COMPOSITES

Acrylic splints provide a stand-alone stabilization technique for many cases of mandibular and maxillary fracture repair. Unfortunately bonding acrylic to teeth is a technique sensitive procedure. At no time can plaque or saliva contact the surface of the prepared tooth or the procedure may fail. Interdental wiring is used in many cases to provide stabilization and ensure incorporation of the splint into something other than the tooth surface. A unique alternative to increase bonding success involves the use of composite acrylic buttons as an anchor.[a] A composite orthodontic button and bracket system is used to accomplish this. A silicone mold on the end of a plastic wand is filled with a flowable composite to accomplish a slight positive meniscus. The mold is placed on a prepared area of the tooth and light cured to achieve bonding. The mold is pulled from the tooth and the button or bracket is left strongly adhered to the tooth surface providing a solid anchor for retention of the acrylic splint. One bracket or button is placed on each tooth to be incorporated in the acrylic. The following series of steps are utilized to manufacture an acrylic splint using this technique.

1. Thoroughly clean teeth. If interdental wiring is to be used as an adjunct to acrylic splint stabilization rather than composite buttons the wire should be placed after cleaning.
2. Flour pumice[b] should be used to thoroughly polish teeth and wire to remove plaque. Any plaque will retard the ability of the acrylic to adhere to the tooth. Fluoride containing pastes will interfere with material setup.
3. Acid etch[c] all tooth and wire surfaces that will come in contact with the acrylic for 30 seconds. The labial surface of the mandibular teeth and the vestibular (buccal) surface of the maxillary teeth are used to avoid occlusion issues. Thoroughly rinse the etchant and dry with an oil free air source.
4. Place a small amount of primer/bonding agent[d] on the tooth surface where buttons are to be placed following manufacturers directions specifically. Bonding agents vary considerably in details of placement.
5. Place flowable composite[e] into the mold, hold the mold against the tooth, light cure for the

recommended time period and pull the mold from the tooth. The author uses an accelerated light cured composite that cures in 5 seconds. As an alternative, fabrication of an anchor can be done without the mold system by adding sequential layers of composite to approximate a similar contour.

6. After the composite buttons have been placed the acrylic splint is applied using a chemical cure self mix acrylic. Cover the proper aspect of the tooth surface for the length of the splint being careful not to involve the gingiva. Ensure a proper occlusion and apposition of fracture ends as the acrylic dries. This is facilitated by preplacement of the endotracheal tube in the esophagostomy site.
7. Rough areas can be smoothed with Goldie[g] or other burs. Oral hygiene should be encouraged if possible to keep the splint free from food and debris. The device should be inspected at regular intervals to ensure that it is intact. Radiographs are taken at 6 weeks to ensure adequate callous formation. The device is removed and the teeth cleaned and polished.

TAPE MUZZLE

Tape muzzles can also be stand-alone treatments for cases of maxillary or mandibular fracture where minimal displacement is present. It may also be used as a salvage procedure to encourage fibrous union in cases where repair is not economically feasible or prognosis for bony union is guarded. This is the case in many bilateral pathologic mandibular fractures secondary to periodontal disease. Tape muzzles are widely utilized and their application described in numerous texts and therefore is not described here.

CONCLUSION

Classic invasive oral fracture repair techniques have led to inadvertent or careless impingement on oral structures including teeth, periodontal ligament, cementum and the mandibular canal and its contents. Young animals are particularly terrible candidates for plates, pins, screws and osseous wiring due to the lack of mandibular bone while teeth are maturing. Cats and small dogs also lack significant bone volume. Avoidance of these invasive techniques should be considered paramount in dogs and cats of all ages. Noninvasive techniques are available to provide excellent stabilization, maximizing patient comfort and minimizing complications. They should be strongly considered as techniques of choice in any mandibular or maxillary fracture in dogs and cats.

SURGICAL EXTRACTIONS

Johnathon R. (Bert) Dodd, DVM, FAVD, Dipl. AVDC
College of Veterinary Medicine and Biomedical Sciences
Texas A&M University, College Station, TX

Although preserving teeth is our goal, extraction is often the best or only option. The decision to extract or preserve a tooth is frequently decided by the amount of homecare the owner is willing or can perform. This information must be discussed with the owner prior to the dental therapy in order for the oral surgeon to appropriately treat and minimize anesthesia time.

Extraction technique is based upon fundamental knowledge of tooth's shape, number of roots and attachment. As a reminder, the only three-rooted teeth in dogs are the upper fourth premolar and the first and second molars (Figure 1). The upper second and third premolars, the lower second, third and fourth premolars and the first and second molars have two roots. All of the upper and lower incisors, cuspids, first premolars and the lower third molars have only one root. In cats (Figure 2), the incisors and cuspids and the upper second premolars have one root; the lower third and fourth premolars, the upper third premolars and the first molars and have two roots. The only teeth with three roots are the upper fourth premolars. Occasionally, the upper second premolar of cats may be absent or have two or three roots.

Before performing the extraction, a radiograph of the tooth will help ascertain information about ankylosed or fragile roots or those that are dilacerated or have abnormal shape. Intraoral radiology is the easiest technique and will give the best detail without superimposition of teeth, but extraoral film may be utilized with additional manipulation of the pet.

Begin the extraction by severing the epithelial attachment at the level of the sulcus with a small scalpel blade or periosteal elevator (Figure 3). With multi-rooted teeth, the furcation should be located. Sectioning of the tooth with a crosscut taper fissure bur (Figure 4) on a high-speed handpiece should begin at the furcation and moved coronally using a brush-type stroke (Figures 5 and 6). This reduces the tooth to single-rooted portions which can be elevated by severing the periodontal ligament. The dental elevator or luxator of the appropriate size is inserted into the space between the root and the alveolar bone. My elevators of choice are the Winged® Elevators (Figure 7) that come in various sizes. The wings are used to severe the periodontal ligament as the instrument is circumferentially rotated around the root using steady, gentle pressure for 10 to 15 seconds to fatigue the ligaments and cause hemorrhage within the periodontal space. The elevator is pressed further apically along the root using a slow twisting action on the instrument while cradling the jaw with the opposite hand. Do not use too much force or a lever action of the elevator. After the loosening the root, the instrument may be pushed to the bottom of the alveolar socket to elevate the root out. Alternatively, the loosened root may be gently grasped with extraction forceps and removed with slight rotational force. If the root cannot be easily withdrawn with the forceps, then more elevation must be performed.

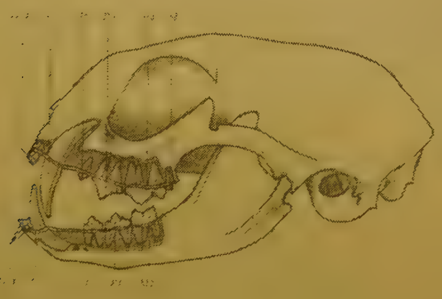

Figure 2. Feline dentition

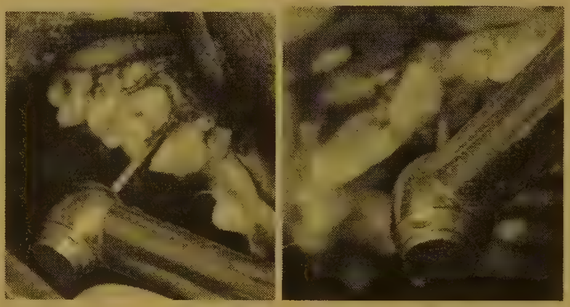
Figure 3. Periosteal elevators.

Figure 4.



Figures 5 and 6. Sectioning 108.

Figure 7. Winged dental elevators

Often times with more difficult extractions one must perform a full-thickness gingival flap and buccal bone removal. After severing the gingival epithelial attachment, two vertical releasing incisions are made on the mesial and distal aspects of the tooth. When removing upper canine (cuspid) teeth, I prefer to make my releasing incisions on the mesial aspect of the canine and the distal aspect of the 2nd premolar (Figure 8). Incisions must also be made in the interdental spaces between the canine and 1st premolar and the 1st and 2nd premolars. The larger flap provides better exposure of the jugal ridge without interference with the gingival tissue. Additionally, the suture lines will not be over a void in the bone. Elevation of the flap is accomplished with a periosteal elevator. The buccal bone covering the root is carefully removed using a round or pear-shaped bur (Figures 8 and 9) on a highspeed handpiece. After removal of the buccal bone from the alveolar margin to approximately ½ the length of the root (Figure 9), the tooth is gently elevated with appropriate size winged elevators or dental luxators on the mesial and distal surfaces to loosen the periodontal ligament (Figure 12).

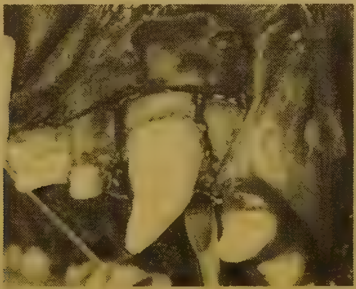

Figure 12. Elevation.

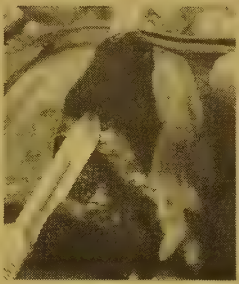

Figure 13. Flap-releasing incision

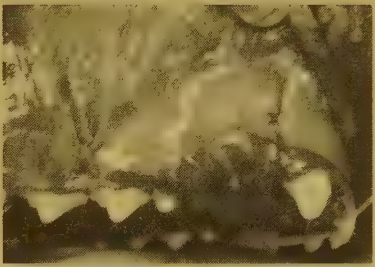

Figure 14. Final closure.

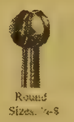

Figure 15.

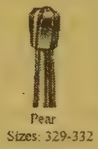

Figure 16.

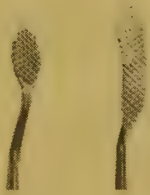

Figure 17. Bone files.

When removing the tooth from the socket, care must be taken to avoid causing an oronasal fistula by rotating the apex of the cuspid into the thin nasal bone. After the tooth is removed, there will be sharp, boney spicules along the alveolar margin. These should be removed with a crosscut bone file (Figure 17) or round bur. Extraction sites from infected teeth should have the soft alveolar socket cleaned of any granulation tissue that may be present at the apex of the socket.

Postoperative radiology should be performed to insure the removal of the entire root and to assess for any bone damage that might have occurred during extraction. Alveolar sockets tend to collapse or fill with soft tissue after tooth removal so the application of an osteogenic material, such as Consil™ (Figure 10 and 11), will help maintain the normal alveolar height. The gingival flap should be sutured to close the defect. Tension on the flap should be removed by passing a scalpel blade across the underside of the flap and severing the first layer of fibers near its attachment (Figure 13). Closure should be accomplished with an absorbable monofilament (not PDS) or braided suture material of appropriate size. Suture patterns may be simple interrupted, cruciate of vertical mattress (Figure 14). Postoperative homecare should include soft diet for a few days, pain medication, oral chlorhexadine rinse and antibiotics (if active infection is present).

FELINE ORAL DISEASES

Johnathon R. (Bert) Dodd, DVM, FAVD, Dipl. AVDC
College of Veterinary Medicine and Biomedical Sciences
Texas A&M University, College Station, TX

PERIODONTAL DISEASE

Periodontal disease is one of the most common diagnoses made in veterinary medicine. A summation of the disease would be that bacteria ("plaque") accumulate on the surface of the teeth, gingival inflammation results, tissue destruction often follows if plaque accumulation is allowed to continue, and local and distant effects can be clinically significant.

Basic definitions that we need to understand are:

- **Dental Plaque***:* A "biofilm" consisting of bacteria, extracellular polysaccharides, cellular debris, leukocytes, macrophages, lipids, carbohydrates and salivary glycans. It attaches to the salivary glycoprotein pellicle that coats the teeth.
- **Dental Calculus (tartar):** Hard deposit often found on teeth, consisting of a mixture of calcium carbonate and calcium phosphate. Calculus is of little importance in absence of plaque. It provides a rough surface to harbor plaque.
- **Gingivitis**: Inflammation of the gingiva. It is considered "reversible": the inflammation disappears if the plaque is removed.
- **Periodontitis**: The destruction of periodontal attachment tissue (connective tissue and bone). This diagnosis is only confirmed when there is *radiographic* evidence of bone loss.
- Halitosis: The result of volatile sulfur compounds that originate from bacterial degradation of amino acids in plaque.

There are six stages of periodontal disease beginning with a healthy mouth and ending with exfoliation of teeth.

In Stage 0, the gingival tissues show no evidence of disease. The oral mucosa is coral pink or shrimp color and the attached gingiva will be firm, resilient and have normal stippling or orange-peel appearance.

In **Stage 1**, there is gingivitis with minimal inflammatory changes, minimal to no change in sulcus depth and up to 0.5 mm sulcus depth, usually due to gingival swelling and not attachment loss.

As the disease progresses to early periodontitis, or **Stage 2,** gingival edema and inflammation of the periodontal ligament occurs. Also, there is onset of crestal bone loss (<25% or <1 mm) and attachment loss with areas of root exposure due to gingival recession.

Untreated periodontal disease will next proceed to moderate periodontitis or **Stage 3.** This stage is characterized by moderate periodontal attachment loss and alveolar bone loss from 25% to 50%. Pocket depth or root exposure increases up to 2 mm. There will be slight tooth mobility.

Stage 4, or advanced periodontitis, is characterized by deep periodontal pockets and root exposure greater than 2 mm with alveolar bone loss greater than 50%. There is moderate to great tooth mobility. There can be extensive root exposure over the canine teeth or the maxillary alveolar bone may have a bulbous appearance around the canines which can progress to osteopenia and gradual extrusion of the canine teeth.

In **Stage 5,** we see exfoliation of teeth, healing of the empty alveolus, recession of inflammation, followed by atrophy of the dental ledge and smooth epithelium covering the gingival surface.

TOOTH RESORPTION (FELINE ODONTOCLASTIC RESORPTIVE LESIONS [FORL], FELINE NECK LESIONS, CERVICAL LINE LESIONS)

An extremely painful disease process seen in cats is odontoclastic resorptive lesions. Prevalence studies have shown that from as few as 20% up to 65% of domestic felines have this very painful condition.[5] Periodontal disease may or may not be present concurrently.

The lesions are classified according to the degree of involvement of the tooth. **Stage 1** lesions are early lesions extending less than 0.5 mm into the tooth's structure. **Stage 2** lesions have significant erosions which do not invade the endodontic system. When the lesion becomes deep erosion invading the endodontic system, it is classified as **Stage 3**. This is followed by **Stage 4** and is characterized as deep involvement causing loss of tooth integrity and more invasion of the endodontic system. Once the crown is lost and gingival overgrowth hides the irregular radiopacities of the roots, it is classified as **Stage 5**.

Stage 1 lesions are generally treated by applying a fluoride varnish to the teeth to desensitize and harden the enamel and to seal any exposed tubules. With **Stage 2** lesions, treatment consists of restoring the tooth with a glass ionomer and applying a fluoride varnish. Realistically **Stage 3 to 5** lesions result in extraction of affected teeth and the root fragments.

Some consideration of crown amputation and retention of root fragments of teeth that are resorbing has been presented. This is best summed up by the following statements:

- "On the basis of clinical, radiographic, and histologic findings of continued root resorption and absence of associated inflammation in teeth without endodontic or periodontal abnormalities, intentional root retention has been proposed as an alternative to whole-tooth extraction."
- "Teeth with endodontic disease or periodontitis and teeth in cats with gingivostomatitis or severe stomatitis should be removed completely."

LYMPHOCYTIC/PLASMACYTIC STOMATITIS (LPS)

Another oral disease of the feline that can cause much frustration is LPS. The etiology is unknown at this point, but bacteria, virus and immune status have all been implicated. This condition is chronic, nonresponsive to oral hygiene, antibiotics, anti-inflammatories, or immunomodulators. The breeds that are most commonly associated with this disease are Siamese, Abyssinian, Persian, Himalayan, Somali and Burmese. Some authors have seen no breed, sex or age predilections. Common presenting complaints of patients with LPS include ptyalism, halitosis, dysphagia, anorexia and weight loss. Clinical signs include hyperemia and ulcerative mucosa with a raspberry or cobblestone appearance. Diagnosis may be tentatively made on the basis of clinical features and lack of response to conventional oral hygiene treatment; however, biopsy is often needed to rule out neoplasia. Viral culture for calicivirus should also be done during the work-up, as this virus may be more important in the disease process than previously thought.

Treatment consists of elimination or control of the excessive inflammatory response by frequent and thorough professional prophylaxis for plaque control, antibiotics and anti-inflammatory drugs. Daily oral hygiene of the cat by the owner is also required. If the cat does not respond well to this treatment and is FELV and FIV negative, then immunosuppressive doses of anti-inflammatory drugs may be required. This may include a dose of 20 mg of methylprednisolone acetate given every 2 weeks for three to six treatments and then as needed. In severe or chronic cases, extraction of the premolars and molars (or all dentition in some cases) may be helpful in resolving the condition. The exception to this is in cats that are positive for calicivirus and have *no periodontal disease* of Stage 2 or greater.

In a study that looked at long-term follow-up of cases treated by dental extractions, it was shown that 60% of the cats were clinically cured, 20% had significant improvement, 13% had little improvement, and 7% had no improvement. These results beg to answer the question as to why are there such variation in results. Could it be that cats with plaque intolerance alone respond to removal of the teeth thereby removing the source of plaque while cats with no plaque intolerance (as evidenced by no periodontal disease of Stage 2 or greater) but carriers of calicivirus do not respond to the extraction procedure? Those cats with plaque intolerance and calicivirus may be the ones with marginal improvement. Food for thought!!

ORAL NEOPLASIA

Squamous cell carcinoma is the most common oral tumor in the cat. It can be either tonsillar or nontonsillar. The tumors are often proliferative, ulcerative, red and friable. It is most often seen in cats older than 10 years of age with no sex predilection. The lesion may resemble gingivitis or appear as a white or pink nodule with progressively mobile teeth due to bony destruction by the tumor. Radiographic bony changes are often seen at time of presentation. Wide surgical resection, in the form of mandibulectomy or maxillectomy, is effective only in early lesions. A poor prognosis is warranted, with only 50% of patients living beyond one year. Tonsillar SCC carries an even poorer prognosis due to its highly aggressive, extremely early rate of metastasis. Radiation has also been employed in selected cases.

Fibrosarcoma, the second most common oral neoplasm in cats, is usually found on the gingiva, palate or mucosal surfaces. It is also characterized by destructive local invasion, with frequent local recurrence and late metastasis

Other neoplasias that rarely occur in cats are malignant melanomas and osteosarcomas. Osteosarcoma of the maxilla and mandible is locally invasive but slow to metastasize, and might be curable with early detection and wide surgical resection. Although oral melanomas are rare in cats, they are as malignant as canine oral melanomas and carry a grave prognosis.

PERRY DONTAL AND THE POCKET OF DOOM (ADVANCED PERIODONTAL THERAPY)

Heidi B. Lobprise, DVM, Diplomate AVDC
Pfizer Animal Health; McKinney, TX

Periodontal disease can vary greatly from patient to patient and even from tooth to tooth in the same mouth. From minimal inflammation and no attachment loss in Stage 1 periodontal disease to the beginnings of attachment loss (up to 25%) in Stage 2, then deeper pockets (up to 50% attachment loss) in Stage 3 and even compromised teeth (greater than 50% loss) in Stage 4, you must be able to tailor the treatment to the problem. Simple steps of a "prophylaxis" must sometimes be supplemented with additional periodontal management.

THERAPY GOALS

Then looking at periodontal disease, therapy is determined by a number of factors, such as the stage of the disease, and the desired outcome. There are several goals to set: (1) Removal of all debris or biofilm (plaque, calculus), (2) Saving the maximum amount of attached gingiva, (3) Minimizing attachment loss, (4) Minimizing pocket depth. Certainly, all foreign material, from bacteria to desquamated cells must be removed from the tooth surfaces and pockets in order to attain healing. Since the attached gingiva is the first line of defense against bacteria, a minimum of 2 to 3 mm is necessary to protect underlying tissues, as the looser alveolar mucosa doesn't afford that protection. The inability to halt attachment loss will eventually lead to tooth loss. Minimizing pocket depth is related to attachment loss, but is a more specific parameter, because pocket depth in itself directly affects the ability for effective home care and maintenance, and deeper pockets can harbor more virulent strains of bacteria. There are even times where excessive gingiva will be removed to decrease pocket depth (hyperplastic gingiva) or the gingiva will be sutured further down the root (apically repositioned flap) for the same effect. Attachment loss without pocket formation occurs when gingival tissue and bone is lost at the same time, exposing the roots and even furcation areas.

Intraoral radiographs are essential, in order to determine the extent and characteristics of bone loss. With recession of gingiva and bone across several roots and/or teeth, a horizontal bone loss pattern will often result in exposed roots. A deeper osseous loss down one root surface, an infrabony pocket may result from the vertical bone loss, and specific therapy may be needed to address that specific defect. These deeper pockets are more difficult to treat and maintain, and anaerobic infections may persist.

PERIODONTAL THERAPY

Periodontal therapy initially concerns itself with removing all plaque, calculus and debris possible. This is of particular importance if there is any attachment loss or pocket formation, because the surfaces must be thoroughly cleaned to help remove the destructive action of the bacteria and moderate the host response as well. Advanced procedures must be undertaken with commitment on the part of the owner as well, because regular home care and frequents follow-up visits will be important

The most effective way to minimize periodontal disease is to prevent it. The USDA has recently granted a conditional license to Pfizer Animal Health for a new product to be used as an aid in the prevention of periodontitis in dogs, as evidenced by a reduction in bone changes (osteolysis/osteosclerosis). This product is a *Porphyromonas denticanis-gulae-salivosa* bacterin, which can be administered to healthy dogs with two initial doses 3 weeks apart. A field safety study was conducted in over 600 dogs of multiple sizes and breeds, and safety was demonstrated in dogs as young as 7 weeks of age when vaccinated according to the label directions. A reasonable expectation of efficacy has been demonstrated in 8-month-old dogs. Duration of immunity for this product has not been evaluated; 6- and 12-month revaccination intervals are currently under evaluation in a field efficacy study. Consultation with a veterinarian is recommended. Additional efficacy and potency studies are in progress.

Practitioners need to evaluate each patient's risk factors for developing periodontal disease. Then they can evaluate the potential risks and benefits of a dental program including the Porphyromonas vaccine. The Porphyromonas vaccine is intended to be only one part of a complete dental program that includes examinations, cleanings and home care.

Supportive Care

Additional care beyond the periodontal work is often necessary to maximize the outcome. Assistance with various antimicrobial agents can help the patient fight off the bacterial onslaught, by using everything from oral rinses and gels to medically appropriate prescriptions of systemic oral antibiotics. Even pain management must be considered, because the conditions alone can be painful, and any surgical procedures must be covered as well.

Root Planing/ Subgingival Curettage

This is by far the most important aspect of periodontal therapy. If the debris is not thoroughly removed from the pocket depths, the disease will remain and intensify. The rounded tip of the curette and its rounded back, make it ideal for subgingival therapy, as opposed to the sharp tip and back of a hand scaler. While certain ultrasonic scalers are modified for subgingival treatments, most are not.

If root surfaces are exposed or if the pocket depth is less than five mm, closed root planing and subgingival curettage may be performed. Using a curette subgingivally with overlapping strokes in horizontal, vertical and oblique directions, root planing removes calculus, debris and necrotic cementum to provide a clean, smooth surface. The curette can also be angled slightly to engage the gingival surface for removal of diseased or microorganisminfiltrated tissues. When pocket depth exceeds 5 mm, or other pathology exists, more invasive procedures are warranted.

Perioceutic Therapy

In moderate pockets of up to 5 mm in depth (and generally deeper than 2 mm), once the area is debrided, placement of a local perioceutic gel containing doxycycline [Doxirobe™ gel (doxycycline hyclate)] can not only provide a direct antibacterial affect against any remaining bacteria, but the anticollagenase activity can help "rejuvenate" the soft tissue of the pocket. Doxirobe gel is not for use in dogs under one year of age, because the use of tetracycline during tooth development has been associated with permanent discoloring of teeth. Do not use in pregnant bitches, as the use of the product in breeding dogs has not been evaluated. The combination of the cleaning and therapy can often help reduce the pocket depth in moderate situations.

The two-syringe system is easily used, but requires some practice. When initially mixing the compounds, make sure the syringes are secure before mixing (100 passes). Once mixed, the material should be placed in syringe. A (place on end to get the most gel into syringe A before detaching) and a blunt tipped cannula placed. The tip of the cannula is gently placed to the depth of the treated pocket, and the material is slowly inserted into the pocket, until a small amount extrudes from underneath the gingival edge. By using light digital pressure on top of the gum, and by gently scraping the cannula tip on the tooth surface, the cannula can be removed without taking the gel with it.

The gel firms up on its own within a minute or two, or a drop of water can be placed on the material to speed up the process. Once firm, the visible material should be gently packed into the pocket, using an instrument such as a W-3, or beaver tail instrument. The owner should be instructed not to brush for about a week in the region (gels and solutions are recommended), nor to pick at the ridge of material that may become visible (light yellow-brown). The material is biodegradable and does not need removal.

Open Root Planing – Gingival Flap

When pocket depths exceed 4 mm but with minimal bone loss or diseased soft tissue that needs removal, a simple flap allows access and improved visibility for open curettage and root planing. Insert the scalpel blade into the sulcus and following the scalloped contour to sever the epithelial attachment. For large areas requiring treatment, vertical-releasing incisions can be made at the mesial and distal ends of the initial incision (at line angles of adjacent teeth). Using periosteal elevator, the gingiva is reflected to expose the root surfaces. A polishing of the root surfaces and irrigation with dilute chlorhexidine follows thorough root planing and subgingival curettage. After repositioning the flap, sometimes further apically down the roots, it is sutured interdentally with absorbable, interrupted sutures. While this procedure is most commonly performed on facial and lingual surfaces, deep pockets on the palatal aspect of the maxillary cuspid teeth can be exposed using a similar technique for treatment.

Reverse Bevel Flap

When the pockets are greater than 4 mm with bone loss and significant amounts of compromised pocket epithelium, a reverse bevel flap is employed to remove the affected gingiva and provide access for thorough cleaning, as long as sufficient attached gingiva is present. With the scalpel blade angled to the alveolar bone, the incision is made into the gingiva, leaving a thin collar of marginal tissue. The flap is elevated, sometimes exposing the alveolar crest, if osteoplasty is warranted. The collar of diseased tissue is removed with a curette, and the root surfaces are completely cleaned, polished and irrigated. Interdental sutures help reposition the gingiva.

Other periodontal procedures may involve pedicle or free gingival grafts to insure that at least 2 mm of attached gingiva is present at a particular site. Bone defect management and guided tissue regeneration strive to return the periodontal structures to a more normal state, and periodontal splinting allows stabilization of loose teeth to encourage reattachment.

GUIDED TISSUE REGENERATION

In an infrabony defect, where the attachment loss has formed a deep pocket in between the root and alveolar bone, inadequate therapy can lead to further attachment, and potentially tooth loss. Guided tissue regeneration (GTR) in dentistry normally deals with the reestablishment and regeneration of periodontal tissues lost due to disease or injury. Tissue regeneration has been demonstrated with alveolar bone, cementum, and the periodontal ligament in specific situations with specific therapies. Typically the soft tissues (gingival epithelium, gingival connective tissue) will grow back into a defect faster than the more important supportive tissues of the periodontium (alveolar bone, periodontal ligament).

A barrier between the instrumented root surface and the gingival flap, can act as a deterrent to exclude the gingival epithelium or gingival connective tissue from populating the root structure. This barrier then provides an area for the progenitor cells of the periodontal ligament and/or alveolar bone to have free access for migration. Because bone develops more slowly than the soft tissue of the periodontal ligament, the ligament should develop first, followed by bony incursion. It is generally believed that periodontal cells have the greatest potential to promote new attachment, but that bone also plays a significant role.

While some barriers are actual membranes, bulk material can also be placed to keep the soft tissue out. When a substance that promotes osseous growth is placed in the infrabony pocket, alveolar bone stands a better chance of filling the defect. There are even products that stimulate periodontal ligament re-growth.

An essential key to such a procedure is adequate exposure and debridement of the area. A gingival flap is necessary to allow for thorough curettage of all material in the infrabony pocket in between the tooth and root, including the removal of any granulation tissue. Once healthy bone and tooth surfaces are clean, the bio-synthetic glass particulate matter is packed into the defect, and the gingival sutured closed.

Postoperatively vigorous home care and plaque control is essential. Antibiotics for up to three weeks post surgically are recommended. Doxycycline is considered a good choice in human medicine because of its antibacterial and anticollagenolytic effects, thus aiding to stabilize collagen locally.[6] Nonabsorbable membranes are normally removed one to nine months following surgery. Materials such as Consil™ (Nutramax Labs) do not need removal.

The entire staff plays an important role in home care. Staff members should be well-versed in available home care products and techniques, so they can aid in demonstrations for the pet owner. Client education can start at a very early stage, introducing new puppy and kitten owners to the concept of brushing as part of a regular grooming and hygiene program. Some pets may be difficult to treat, and the risk of injury to the owner should not be assessed in recommending home care. It is important to make sure from the start that the commitment is there for the advanced procedures.

Equipment

Many standard pieces of equipment and supplies can be used, including scalpel blades (15C works well), scissors (sharp/sharp for gingival remodeling), and sutures (usually absorbable, from 3-0 to 5-0). Full evaluation is not possible without the use of a periodontal probe/explorer to ascertain pocket depths, and intraoral radiography is essential to get a complete picture of the situation, whether there is periodontal bone loss or for pre-extraction (and post-) radiographs. Other essential tools include periodontal curettes for scaling root surfaces, periosteal elevators (Molt No. 2 or No.4) for elevating gingiva, good elevators (winged elevators are especially helpful), and some means of sectioning teeth.

Refining Your Skills

Periodontal surgery. While most practitioners provide dental services to their patients, they seldom cut the gingiva to provide sufficient exposure for adequate treatment. Opening gingival flaps takes little additional skill, just the ability to know where to make the flap and proper tissue handling technique. In pockets less than 5mm, a periodontal curette, with its round toe and rounded back, is very useful for closed root planing and subgingival curettage where no flap is needed.

Any time a periodontal pocket is deeper than 5 mm, the area must be exposed for adequate cleaning. With the periosteal elevator, an envelope flap can be made by lifting the gingiva directly over the defect, and extending it the distance of 1 to 2 teeth on either side to provide enough exposure. This can stretch the tissue out significantly if the pocket is deep, or the area is too wide. Therefore, a flap can be created by making diverging incisions mesially and distally to the defect, through the attached gingiva past the mucogingival line into the alveolar mucosa. The periosteal elevator is then used to lift the flap off the alveolar bone, providing access to the site. Sufficiently elevate for adequate exposure, but don't expose any more bone than is necessary.

Once the site is laid open, every effort must be made to clean out all debris and granulation tissue from the pocket, particularly in pockets that extend down the root of the tooth, in between the tooth and alveolar bone (infrabony pocket - vertical bone loss). Once cleaned, material such as Consil can be used to help promote osseous healing and discourage soft tissue growth into the area. This form of therapy (guided tissue regeneration) can be of particular importance with deep pockets at the palatal aspect of maxillary canines, and with deep infrabony pockets involving the lower first molar that can compromise mandibular strength. While the lower first molar defects can often be exposed using standard releasing incision flaps, the deep palatal pockets provide additional challenges. It is essential in this area to design a flap and plan sutures that will bring the gingival margins snugly against the tooth, to protect the materials in the pocket. Mesial and distal releasing incisions can be made extending out from the canine towards the adjacent teeth, on the gingival papillae. Exposure with this method can be somewhat limited, like an envelope flap, and closure involves using a sling suture technique, running the suture in a semi-circle pattern within the palatal mucosa from a mesial to distal direction. Then exiting distal to the canine and re-entering near the same site, reversing the semi-circle pattern to exit mesial to the tooth. Finally tying off the two ends which tightens the flap against the tooth. Incisions made directly into the palatal mucosa not only can cut the palatine artery, but make a flap that is more difficult to hold against the canine.

An alternate method is making a crescent-shaped flap in the palatal mucosa, extending from a point just mesial to the canine in the incisor-canine interdental space, and running medial to the canine to a point just distal to it. When the flap is elevated, there will be hemorrhage from the rostral severing of the palatine artery, but it can be tied off at that extent and preserved within the flap itself. Once elevated, good exposure allows for thorough cleaning of the infrabony pocket. Exercise to avoid puncturing the remaining alveolar bone separating the pocket from the nasal cavity (oronasal fistulation), or the tooth will need to be extracted. Once the pocket is cleaned and filled, simple interrupted sutures can hold the crescent flap in place.

If some gaps appear, a small amount of the mesial extent of the flap can be trimmed, to bring the gingival margin closer to the tooth. Sutures can be placed to join the cut edge of the flap back to the palatal mucosa, as long as no tension is placed on the flap that would cause it to pull away from the tooth. A small gap between the cut edge of the flap and the remaining palatal mucosa will typically heal without complication.

In some areas there will be horizontal bone loss and suprabony pockets (bone loss occurs at same level of attachment loss but no defect in between the tooth and alveolar pocket). Once the area is exposed, all root surfaces areas should be thoroughly cleaned using curettes. In some cases, if the bone loss includes interdental spaces, the flap can be sutured in place so the gingival margin is actually placed further down the root than originally positioned (apically repositioned flap). This can help minimize the pocket depth, though the actual level of attachment is still the same, just more root structure is left exposed. These sites are not amenable to osseopromotive products.

INTRAORAL RADIOLOGY STANDARD OF PRACTICE

Heidi B. Lobprise, DVM, Diplomate AVDC
Pfizer Animal Health, McKinney, TX

Intraoral radiology may have once been considered a special service or luxury, but as practices continue to offer expanded dental services, this means of diagnosis is a vital tool assisting in the diagnosis, treatment planning, and monitoring of oral disease.[1] Diagnostically, being able to assess normal anatomy helps to determine if abnormalities exist, including variations in development (missing or aberrant teeth) or acquired diseases that may affect the bone and tooth structure (cranial mandibular osteopathy or CMO, hyperparathyroidism, neoplasia).[2] When determining the possible treatment for problems such as feline resorptive lesions, endodontically compromised teeth, and periodontal disease, radiology can help the practitioner make a more accurate assessment. Preoperative radiographs can help monitor extractions by revealing abnormal root structures, impacted teeth, and ankylosed roots. Postoperative films check treatment success. Endodontics requires several films during the procedure to evaluate routine treatment and reveal complications.

EQUIPMENT

Films

For dental films, extraoral non-screen as well as panoramic products may be used, but for greatest versatility, the smaller, non-screen intraoral films are most useful. Occlusal films (No.4, DF50 or EO41) are 2 1/4 X 3 inches in size and often used for imaging the incisal areas, both mandibular and maxillary and larger cuspid teeth. Due to restrictions of the palatal vault or intermandibular space, smaller films can be placed more readily to radiograph premolars and molars. The periapical films (No. 0 – EP01, No. 1 – EP-11 and No. 2 – EP-21) range from 7/8" x 1 3/8" to 1 1/4" x 1 5/8". Proper placement of the film packet with accurate positioning technique can provide isolation of a specific tooth with excellent detail. This detail is enhanced by the fact that intraoral film is non-screen, double-coated emulsion film. A raised dot imprinted on the film and packet indicate the side that should face the x-ray tube, placing the concave "dimple" away from the tube. Once developed, this dot helps determine the orientation and identification of the teeth. The film is encased in an inner black paper sheet with a layer of lead foil on the backside that reduces backscatter from deeper oral tissues, all in a plastic or paper cover. The flexible films may be held in the mouth by just closing the occlusion, or with the help of plastic holders, hemostats, rubber bands, or malleable materials (modeling clay) in plastic bags. Most digital radiographic sensors are similar to a size No. 2 film though smaller ones are currently available, and a sensor similar in size to the #4 films is being developed.

Radiographic Unit

As a veterinarian's dental skills improve and he or she begins to perform more advanced procedures such as endodontics, radiology increases in importance. To facilitate the use of radiology, a dental x-ray not only will prove to be invaluable, but will often help the practice financially, with increased use. If you can place the smaller dental unit near the area where procedures will be performed, that greatly enhances its convenience. The maneuverability of the x-ray head facilitates angulation for positioning techniques. The position indicating device (PID) or cone may vary, depending on the machine. Most units produced for veterinary use have customized dental 'map', so the region or tooth being imaged can be selected for appropriate exposure time (most have a set KVP of 70). The "F" number may need adjusting, depending on the intensity of the individual unit's exposure or if the unit is to be used with a digital sensor. Digital sensors typically need a much shorter exposure time than typical intraoral films.

After appropriate installation, registration, and calibration, the extent of scatter can be determined, but is usually minimal 6 feet away from most dental radiographic units, as long as the area directly in the path of the beam is avoided. Appropriate protective measures for both operators and patients should be observed.

Although less convenient and more challenging to obtain diagnostic radiographs, intraoral films (D-speed/Ultraspeed; Kodak) can be used with a standard x-ray machine using a technique of 100 mA and a focal distance of 12 inches (1/10th to 1/15th second) or 36 inches (2/5th to 3/5th seconds). The KVP will vary from 65 for a cat or toy dog, 70 for a small dog, 75 for a medium dog, 80 for a large dog, and up to 85 KVP for a giant breed.[4] With these parameters as a general guide the practitioner for their specific equipment can develop an appropriate technique chart. With E-speed film (Ektaspeed, Kodak), the exposure time can usually be reduced by half. There is some loss of contrast and these films are not recommended for development in some chairside developers (check manufacturer's recommendations).

TECHNIQUE

The appropriate positioning of the film and beam is often the most challenging aspect of taking intraoral radiographs. Be sure to get good, practical instruction on taking radiographs once you have obtained a unit. It is often much easier to learn about positioning and making adjustments with a digital unit, as the image is immediately available for review, and any changes can be made as soon as the image is displayed.

While a parallel technique (film and object parallel and x-ray beam perpendicular to both) would be ideal to minimize distortion, most areas of the oral cavity do not lend themselves easily to this positioning. The only region where the film can be placed parallel to the teeth is that of the mandibular premolars and molars, with a corner of the film pressing into the intermandibular space. The most mesial (rostral) roots and teeth may not be visible on this view, as the film may be limited by the mandibular symphysis, but aiming the radiographic beam from a slightly rostral oblique position may allow these roots to be imaged.

For the rest of the teeth in the oral cavity, parallel positioning is not possible, so a film is placed as close to a parallel plane to the object (root or tooth) as possible. Remember to center the film on the region to be assessed, such as the alveolar bone ridge for assessment of periodontal bone loss. Note – if it looks like there might be periodontal bone loss, but some tooth structure is 'burned out" or dark, retake the radiograph using a slightly lower setting (shorter time). If the roots are to be imaged, be sure the film is positioned further towards the roots, not necessarily the crown.

Once placed, one option is to use a bisecting angle technique for these films by aiming the beam at a line that bisects the angle formed by the long axis of the object (tooth) and the film. Another way of determining beam position is to first line up the beam (or similar object such as a 2-inch roll of tape or tongue depressor) perpendicular to the film. This would result in an image that is too short (shadow of a tree at noon). Next, line up the beam perpendicular to the root (tooth); this image would be too long (shadow of a tree at daybreak). Then, split the difference between these two positions, and the resulting image will be approximately the same size as the object, thus minimizing the distortion (and the beam will be perpendicular to that bisecting line mentioned earlier). Helpful devices, such as connecting two tongue depressors with a brad, or even using the handles of a small pair of forceps, can help you visualize the two positions (perpendicular to film; perpendicular to tooth), so you can aim the beam halfway between the two. This perspective will also help you make appropriate adjustments to an image; if you want to make the image shorter, move the beam to a position more perpendicular to the film. This can be helpful when trying to image a long canine tooth or the roots of a large upper forth premolar on one film, by shortening the image on purpose.

One challenging site to radiograph can be the maxillary premolars in a cat. Even with using the above techniques, the shape of a feline head and position of the zygomatic arch can make it difficult to get a reasonable image of the premolars. The angles of the head of a cat may also result in tooth overlap, so you may start by visualizing what would be a 'straight-on' shot by looking through a two-inch roll of tape, and adjusting the beam from there. If the general positioning is adequate, but the zygomatic arch is still in the way, you can elongate the image on purpose (move the beam more perpendicular to the tooth), which will distort the teeth slightly, but may allow you to evaluate more of the roots.

An alternate method involves using a small mouth gag to prop the mouth open, with a towel underneath the cat's head. With a slight shift in the position of most cats' heads, you can adjust the arcade on the downside to the teeth are nearly parallel to the table surface. Then place the film underneath the head, towards the dorsal aspect of the head. In this position, aim the beam obliquely across the head in order to capture the image of the downside roots (picture where the beam will hit the roots, then the film, and make sure the film is positioned correctly), and take the film. If the upside maxillary premolars superimpose the downside premolars, the angle of the beam needs to be slightly increased. This extraoral technique can also be helpful when assessing the mandibular first premolars in dogs, and even the maxillary premolars in brachycephalic patients.

Each of these positions has been described for positioning with a dental radiographic unit with a mobile positioning arm. If a standard radiographic unit is to be used, the patient's head should be adjusted halfway in between the two positions that would have the beam aimed perpendicular to the film, and perpendicular to the tooth. Another way to look at this is if the film was parallel to the table (perpendicular to the beam), the image would be too short, and if the tooth root was parallel to the table, the image would be too long, so split the difference (see Radiographic Unit section above for techniques).

Extraoral studies may be used, both in parallel and bisecting techniques, for survey films, to assess massive oral injuries, fractures, neoplasia, or temporomandibular studies. However, in dealing with select structures and teeth, extraoral radiology often cannot provide sufficient detail or accuracy due to superimposition of structures or distortion. Intraoral films offer better dental isolation as well as the enhanced detail of non-screen film. The films are relatively inexpensive, and can be developed quickly in rapid dental developer/fixer solutions.

Film Development

If intraoral films are to be used, a chairside developer will facilitate development. The film packet is opened under appropriate light restrictions and the film placed in a film clip, either metal or plastic, or a hemostat. After immersing in water for 5 seconds to hydrate the emulsion, the film is place in the developer with initial agitation for 15 to 60 seconds (depending on solution and temperature). Following a water rinse, the film is then placed in the fixer solution with intermittent agitation for approximately twice the developing time. After a final water rinse, initial assessment can be made. The film holders may be suspended for drying or placed in a film drying stand. Film identification can be facilitated by the used of radiopaque ID numbers placed on the film before the exposure or with marking pens after drying. Films may be displayed in cardboard mounts, plastic mounts, or stored in dental envelopes

FELINE PRURITUS – SCRATCH IT LIKE MAD!

John C. Angus, DVM, Diplomate ACVD
Animal Dermatology Clinic, Pasadena, CA

WHAT IS PRURITUS?

Pruritus is medical term derived from the Latin prurire meaning itch. Samuel Hafenreffer defined pruritus 340 years ago as "an unpleasant sensation provoking the desire to scratch." If you feel an itchy sensation, you scratch near it in order to change your perception of that sensation. Since our patients might rub, lick, scoot, chew, roll, or shake, as well as scratch, we must expand the definition. Indeed, the most common expression of pruritus for cats is obsessive grooming, not scratching. Just to be extra difficult, cats are notorious for exhibiting this behavior in front of owners, who never see them lick but present a cat with hair perfectly barbered off in beautiful symmetry.

Threshold

Pruritic mediators or sensations are not equal in their ability to elicit itch. If sensation exceeds threshold you itch, otherwise you don't. The same stimulus may or may not induce pruritus depending on the individual threshold and the circumstances that influence their threshold at that moment.

Modulation

Psychological state can raise or lower threshold. Activity or other stimulation can distract a patient from scratching without changing the pruritic mediators or sensation. When left alone an atopic cat may lick rhythmically for hours, but when the family comes home, another cat is introduced, or food is present, they stop grooming immediately. When the house becomes quiet and dark at night, the cat returns to licking or scratching. Some itch so intensely that no amount of stimulation or physical restraint distracts them. Parasites, herpes, and food allergy can stimulate self-mutilating pruritus. We can modulate psychological states to reduce pruritus by recommending environmental enrichment.

Summation

Multiple stimuli can add up to exceed threshold and worsen the severity of pruritus. For example, an atopic cat may not itch when exposed to ragweed pollen alone, but becomes pruritic when secondary factors such as dry skin, fleas, or bacterial infection are present. With secondary factors, patients may require high dose steroids to control pruritus. By preventing fleas and treating infection, pruritus is more easily managed with relatively safe drugs. A corollary is that failure to manage these amplifying factors results in treatment failure no matter how aggressively or appropriately the primary disease is treated. Our job is to identify and manage as many primary and secondary causes for itch, do our best to raise the threshold, modulate sensation, and eliminate factors that contribute to summation.

RECOGNIZING PRURITUS IN CATS

Some clinical signs of pruritus are obvious: for example, scratching the face, head, ears, and neck, with hind claws to the point of excoriation and self-mutilation (Table 1). Cats that "chew," "corn-cob," or "pull" hair with their teeth also are easily recognized. If pruritus is accompanied by visible evidence of inflammation or dermatitis, such as scale, crust, erythema, papules, plaques, or erosions, then clients and veterinarians are much more likely think pruritus. The difficulty arises when the only evidence is alopecia subsequent to excessive grooming, especially when the cats do not groom in front of owners. In many cases symmetrical alopecia of the flanks, ventral abdomen, limbs or tail, is the only sign of significant pruritus. Some cats have primary lesions, such as miliary dermatitis, eosinophilic ulcers/plaques/ granulomas of lips or haired skin, alopecia and scale on pinna, facial seborrhea, often associated with diseases that cause pruritus, but never appear to itch. The diagnostic approach to these cases is the same as the approach to pruritus, even if itch is not the most prominent clinical sign.

Differential Diagnoses

There are dozens of diseases that can cause cats to itch; however, 95% of cases will result from a smaller more manageable list caused by PAIN: Parasite, Allergy, Infection, Neoplasia.

- Parasite: Notoedres, Cheyletiella, Otodectes, Fleas, *Demodex gatoi*, Lice, Chiggers.
- Allergy: Atopy, Food, Contact, Mosquito bite hypersensitivity, Eosinophilic granuloma complex
- Infection: Bacteria, Malassezia, Dermatophyte, Herpes viral dermatitis
- Neoplasia: T-cell lymphoma

Less common primary causes of pruritus which should be included on a list of differentials for unusual cases or when the more common causes have been

Table 1. Clinical Manifestations of Pruritus

Primary Clinical Signs	Secondary Lesions	Associated Lesions
Scratching	Excoriation	Miliary dermatitis
Chewing	Scale	Ulceration
Corn-cobbing	Crust	Plaque
Licking	Erosion	Erythema
Excessive grooming	Hypotrichosis	Granuloma
Hyperesthesia	Symmetrical alopecia	Seborrhea

eliminated, include hyperthyroidism, drug eruption, vasculitis, erythema multiforme, urticaria pigmentosa, pemphigus foliaceus, and cholestasis.

Symmetrical Alopecia: Clinical Presentation, Diagnosis, and Management

A common presentation that is illustrative of my approach to feline pruritus is symmetrical alopecia due to excessive grooming. The cat tongue is a very efficient instrument to break off and remove hair shafts at the surface of the skin. The broken hair shaft remains in the hair follicle and are easily visible on physical examination. Examination of hair shafts under the microscopic demonstrates fractured ends, easily differentiated from the tapered end of a normal hair. Owners may or may not observe the patient grooming excessively. Swallowed hair may manifest as hairballs, frequent regurgitation, vomiting, or hair in stool. Scale or other evidence may be effectively removed by the patient. In most cases skin is quiescent, with no visible scale, crust, erythema, papules, pustules, or erosions.

This type of pruritus is frequently misdiagnosed as psychogenic alopecia based solely on clinical appearance. Excessive grooming is more commonly the result of pruritus than anxiety or obsessive-compulsive behavior disorders. In a recent study, evaluating 21 adult cats referred to a behavioral service with a presumptive diagnosis of psychogenic alopecia, a cause for pruritus was identified in 19 cats, with only 2 cats found to have only psychogenic cause. Adverse food reaction was the most common diagnosis, 12 cats confirmed by challenge feeding and 2 additional cats suspected but not confirmed. Other causes identified in this population included parasitism, flea allergy dermatitis, atopy, and hyperthyroidism. Psychogenic alopecia should only be diagnosed when all causes of pruritus have been eliminated from the list of differential diagnosis. The list of differential diagnoses can be intimidating and the ability to arrive at a definitive diagnosis can be difficult; however, achieving a final diagnosis and directing therapy at the cause of the itch is much more rewarding for patient, owner, and veterinarian than treating all causes of itch symptomatically with frequent steroid injections.

History

History is useful to rank differential diagnoses but rarely provides a diagnosis.

- **Determine the age of onset of clinical signs.** If less than 6 months, consider parasite hypersensitivity and dermatophytes the most likely cause of disease. Between 6 months and 6 years of age, any cause for pruritus is possible, with ectoparasitism, atopy, and food allergy the most likely differentials. In cats greater than 8 years of age, consider cutaneous T-cell lymphoma or hyperthyroidism.
- **Determine if the condition exhibits a high degree of seasonality.** If year round, you can not eliminate or even lower atopy on the list, since atopy may be non-seasonal; however, if there is a high degree of seasonality with extended periods of normalcy during predictable and repeatable cycles, then atopy is most likely, followed by seasonal insect triggers such as fleas and mosquitoes.
- **Determine if the condition was responsive to corticosteroid therapy.** As a general rule, atopy is highly responsive to steroids, parasite hypersensitivity is partially or temporarily responsive, and poor response to steroids is suggestive of food allergy.
- **Determine if lifestyle increases risk for contagious causes of pruritus,** such as Otodectes, Cheyletiella, fleas, or dermatophytes. Examples include a recently introduced animal, recent travel, or access to the outdoors.

Initial Diagnostic Approach

The initial approach should be aimed at finding parasites early, eliminating need to pursue other tests.

- Flea combing, ear swabs, acetate tape preparations, skin scraping and hair pluck in mineral oil to evaluate for Fleas, *Demodex gatoi*, *Otodectes*, and *Cheyletiella*. *D. gatoi* mites are the most elusive. Target hair pluck and deep and superficial scrapings on any area with inflammation or easily epilated hairs. If no areas exist, sample broadly across several regions; include areas the cat cannot reach easily, such as the back of the head and neck. Lower the condenser on the microscope to increase refraction and to avoid blasting light through the unstained mites.
- Performing skin scrapes on non-pruritic cats from the same household may yield positive results, since these cats don't care about their parasite burden and are not removing mites as efficiently.
- Fecal exams, because cats that are so efficiently grooming mites from skin may yield negative scrapes.
- If no mites or fleas, perform a Wood's lamp examination and collect dermatophyte culture.
- Begin to discuss food allergies and environmental allergies as the next focus once parasitism and dermatophytosis are definitively ruled out.

Parasite Treatment Trial

A parasite treatment trial is recommended for all pruritic cats. Remind owners that the absence of parasites on initial samples does not eliminate ectoparasites from the list of differential diagnoses. Selamectin applied topically every 2 weeks for three treatments is an effective protocol. Selamectin treats for fleas and Otodectes, and is anecdotally beneficial for Notoedres and Cheyletiella although not rigorously evaluated. Oral or injectable ivermectin provides no substantial advantages over selamectin and is not effective against fleas. Fipronil spray is effective against Cheyletiella, as well as fleas, but not Otodectes. Unfortunately no avermectin is consistently effective against *Demodex gatoi*. For *Demodex gatoi,* use Lime

Sulfur dip (8 oz/1 gallon) once weekly for 4 to 6 weeks. Although time consuming and malodorous, Lime Sulfur is safe, effective, mildly anti-pruritic, and has the added benefit of efficacy against dermatophytosis. A treatment trial with Lime Sulfur is the only method to rule out *Demodex gatoi*. In a multi-cat household, treat all animals to eliminate the possibility of repeat infestation during the treatment trial. If not possible to treat all in-contact animals, then the patient should be quarantined for the duration of the treatment protocol. If not parasite or dermatophyte, then consider food allergy, atopy, and hyperthyroidism.

Food Trials

A comprehensive elimination diet trial should be implemented as a diagnostic test. For a minimum of 8 to 12 weeks, the patient should be provided only an appropriate novel protein or hydrolyzed protein diagnostic test diet. The author prefers Rabbit/Green pea or any of the many hydrolyzed protein diets. Other pets may need to be isolated and dishes removed since even licking empty food dishes could provide enough of the offending protein to perpetuate pruritus and invalidate the diet trial. Stress to the owners that the diet food is not what makes their cat better; rather it is the absence of any offending proteins that is necessary for improvement. Furthermore, the diagnostic value of a diet trial is not how much better the cat gets while on the food, but whether or not clinical signs return when challenge fed with the original diet. Food trials can be performed concurrent with parasite treatment trials, since the diagnostic test is response to provocative challenge.

Allergen Testing

The purpose of specific allergen testing is to identify environmental allergens for inclusion in allergen immunotherapy injections, not to diagnosis atopy. Most cats will have several positive reactors by intradermal allergy testing or IgE allergy serology, but that does not mean those environmental allergens cause their disease. In cats with distinct seasonal pruritus or cats where other causes, such as parasites, dermatophytes, and food allergy have been eliminated, intradermal allergy testing or IgE allergy serology is appropriate. Selection depends on access to intradermal testing, ability to remove patient from medications that inhibit intradermal testings (antihistamines, corticosteroids), and safety of sedating patient. Serology is an acceptable substitute for intradermal allergy testing, if conditions for intradermal allergy testing cannot be met. Regardless of method, immunotherapy should be instituted with the understanding that this therapy is not immediately anti-pruritic. Rather, immunotherapy modulates immune response to allergens, decreasing severity of hypersensitivity reactions. This is a long-term therapy that diminishes clinical signs, but may not eliminate all manifestations of disease. The safety record for immunotherapy is excellent.

THERAPY

In addition to attempting to identify and manage the primary cause, therapy can be instituted to provide temporary relief of clinical signs; commonly referred to as symptomatic management. Basic therapies include cooling, topical sprays/lotions, omega III fatty acids, antihistamines, corticosteroids, and cyclosporine. Cooling methods commonly applied to dogs, such as frequent cool water baths, oscillating fans, menthol, or witch-hazel sprays, are less useful for cats since they may not be readily accepted by the patient. Topical sprays and lotions may also be resisted by some cats, but can provide benefit if the cat is not permitted to groom after application. Prolonged usage of potent topical steroids (betamethasone, dexamethasone, triamcinolone) can have severe adverse effects, including permanent skin thinning and hyperfragility. Topical steroids should only be used for short periods.

Oral omega III fatty acids and antihistamines may be beneficial in a mildly pruritus, but are less likely to provide satisfactory results in severely affected patients. Data on use in cats is woefully inadequate. Omega III fatty acids, should not be used during a food trial, since fish is a common dietary protein in cats. The dosage of EPA (eicosapentanoic acid) should be approximately 180–200 mg/day. Alone, fatty acids are not likely to substantially reduce pruritus; however in combination with other therapies fatty acids can be beneficial, even reducing the amount of corticosteroid required. Antihistamines are most useful for atopy, with minimal benefit if any in other pruritic diseases. Table 2 provides a list of antihistamines used in cats and suggested doses. Antihistamines are very safe, with minimal side effects or contraindications. Failure to respond to one antihistamine does not mean the patient wouldn't respond to a different antihistamine. Try several in two week trials before abandoning hope.

Table 2. Suggested Antihistamine Dosages for Cats

Chlorpheniramine maleate	0.25 mg/kg up to TID
Clemastine (Tavist®)	0.05 to 0.1 mg/kg BID
Cyproheptadine (Periactin®)	0.5 to 1.0 mg/kg up to TID
Hydroxyzine HCl (or pamoate) (Atarax®)	1.0 to 2.0 mg/kg up to TID
Amitriptyline	5 to 10 mg/cat SID or divided BID

Corticosteroids are the most effective method of providing immediate and substantial relief from symptoms. Therapy should be designed to provide temporary humane relief from refractory pruritus, but never as a substitute for appropriate diagnosis and management of primary disease and secondary infections. Long term glucocorticoids can have disastrous consequences, including increased risk for secondary infections, diabetes, and most horrifically feline cutaneous hyperfragility syndrome, characterized by thin fragile skin that tears very easily and very permanently.

When using glucocorticoids to manage pruritus, the least amount needed to provide relief, for the shortest period of time is the rule. Because cats are slow to convert prednisone to metabolically active forms, always use prednisolone or methylprednisone directly. If a cat fails to respond to appropriate prescribed dosage, verify that prednisone was not dispensed inadvertently. Oral triamcinolone and dexamethasone are acceptable for short-term usage in cats. Our knowledge of the metabolism of the various synthetic corticosteroids in veterinary patients is not adequate. Most information on absorption, half-life, and relative potency is extrapolated from human literature. A recent study comparing glucocorticoids at immune suppressive doses in cats, supported the hypothesis that dexamethasone had higher diabetogenic effects than prednisolone. This may be due to a variety of factors, but suggests that if long-term high-dose steroid is necessary for managing a feline patient, prednisolone is preferred over dexamethasone. In general, use oral steroids at high initially daily dosage to suppress pruritus, then diminish to the lowest alternate-day dose that maintains symptoms. Use of steroids in combination with oral antihistamines may extend the time between doses or lower the overall amount of steroid necessary to maintain satisfactory clinical response. Depo-Medrol (methylprednisolone acetate) is recommended primarily for management of eosinophilic granuloma complex or in atopic cats where other diagnostic and therapeutics have been exhausted.

Microemulsified cyclosporine provides an alternative to corticosteroids for cats that require long-term symptomatic management, or who fail to respond satisfactorily to management of the primary disease. Although anecdotally effective at 5 mg/kg daily for pruritus and eosinophilic granuloma complex, cyclosporine has not been rigorously evaluated in cats. In general, cyclosporine does not provide the rapid cessation of pruritus achieved with corticosteroids, but can be used for long term treatment with relatively fewer adverse consequences. Nausea, inappetence, and vomiting are the most common side effects. Fatal systemic toxoplasmosis has been reported. Avoid use in cats with high risk for toxoplasmosis, such as hunters. Toxoplasmosis titers can be performed prior to administration.

Allergen-specific immunotherapy (ASIT) provides a non-drug option for long-term treatment of atopy. While not directly antipruritic, ASIT modulates response to allergens and diminishes severity of hypersensitivity reactions. The precise mechanism of action is not known; however, the safety record is very good and there is excellent evidence for efficacy. Response rates as high as 70% have been reported for ASIT in feline patients. Cats may require adjunctive therapy, such as antihistamines or intermittent corticosteroids, for maximal benefit. Either intradermal allergy testing or serum IgE allergy serology is appropriate methods for determining which allergens should be included in therapy.

CANINE PRURITUS – PRACTICAL GUIDE TO MANAGEMENT

John C. Angus, DVM, Diplomate ACVD
Animal Dermatology Clinic, Pasadena, CA

WHAT IS PRURITUS?

Pruritus is medical term derived from the Latin *prurire*, meaning itch. Three hundred and forty years ago, Samuel Hafenreffer defined pruritus as "an unpleasant sensation provoking the desire to scratch." If you feel an itchy sensation, you scratch near it in order to change your perception of that sensation. Since our patients might also rub, lick, scoot, chew, roll, or shake, or press their backs up against the coffee table as well, we must expand the definition to include these other symptoms.

Threshold

Pruritic mediators or sensations are not equal in their ability to elicit itch. If sensation exceeds threshold you itch, otherwise you don't. The same stimulus may or may not induce pruritus depending on individual threshold and the circumstances that influence threshold at that moment.

Modulation

Psychological state can raise or lower threshold. Activity or other stimulation can distract a patient from scratching without changing the pruritic mediators or sensation. When left alone an atopic cat may lick rhythmically for hours, but when the family comes home, another pet is introduced, or food is present, they stop itching immediately. When the house becomes quiet and dark at night, the dog returns to licking or scratching. Some itch so intensely that no amount of stimulation or physical restraint distracts them. Sarcoptes and food allergy can stimulate self-mutilating pruritus. We can modulate psychological states to reduce pruritus by recommending environmental enrichment.

Summation

Multiple stimuli can add up to exceed threshold and worsen the severity of pruritus. For example, an atopic dog may not itch when exposed to ragweed pollen alone, but becomes pruritic when secondary factors such as dry skin, fleas, or bacterial infection are present. With secondary factors, patients may require high dose steroids to control pruritus. By preventing fleas and treating infection, pruritus is more easily managed with relatively safe drugs. A corollary is that failure to manage these amplifying factors results in treatment failure no matter how aggressively the primary disease is treated. Our job is to identify and manage as many causes for itch as possible, then do our best to raise the threshold, modulate sensation, and eliminate factors that contribute to summation.

TOP FIVE PRIMARY CAUSES OF PRURITUS IN DOGS

1. Atopy
2. Food allergy
3. Parasite hypersensitivity (fleas, Sarcoptes, Cheyletiella, or Otodectes)
4. Malassezia dermatitis
5. Staphylococcal pyoderma

To make it even easier, Malassezia dermatitis and Staphylococcal pyoderma are almost always complications of atopy, food allergy, or parasite hypersensitivity. You just need to do cytology to determine #4 and #5, treat, and then only worry about #1–3. Less common causes of pruritus include actinic dermatosis (sun damage), cutaneous larval migrans, contact reactions, adverse drug reactions, biting flies, dermatophytosis, T-cell lymphoma, vasculitis, and pemphigus, cholestasis

DIAGNOSIS

History

None of the top five causes for pruritus can be definitively ruled in or out by history, but they can be ordered differently based on history:

- **Age of onset?** If less than one year, think parasite hypersensitivity or Demodex. Between 1 and 4 years of age, anything is possible, but atopy is number one. Over 6 years of age, food allergy becomes more likely than atopy, but also start thinking hard about endocrinopathies.
- **Seasonality?** Definite seasonality is usually atopy or flea allergy dermatitis. Year-round pruritus doesn't eliminate atopy or flea allergy, but you get to pile on other differentials.
- **Higher risk for parasite exposure?** Recent adoptee in household? People or other animals in household itching?
- **Regular flea/tick control?**
- **Previous treatment?** Antibiotics/steroids/thyroid supplementation? Response? If highly steroid-responsive bump up atopy. If not steroid-responsive, bump down atopy and bump up food allergy, endocrinopathies, and unusual dermatoses such as T-cell lymphoma or erythema multiforme.

Breed

Not particularly useful, but can lead you astray, convincing you that a fox terrier has to be atopic when it really just has Sarcoptes (don't worry it will develop atopy later). Breed predisposition lists are over long, change based on breed popularity, change geographically, and change over time often enough to be rendered nearly meaningless. Any dog can be atopic, food allergic, acquire parasites, or become overpopulated with native Malassezia and/or Staphylococcus. Ignore breed and approach all itchy dogs the same.

Physical Examination

Atopy and food allergy look identical in the exam room, but two areas to look for atopy are the anterior flexural surface of elbow and the posterior carpus between pad and accessory carpal pad. Flea allergy tends to affect the back half of the dog worse, with classic signs of alopecia, erythema, papular dermatitis at dorsal tail head. Sarcoptes is most commonly associated with the pinna, elbows, flank; but not always. Never rule out Sarcoptes based on physical examination alone. Any dog that itches can be a Sarcoptes dog. Cheyletiella is usually indicated by dry scale on the dorsum. Check for a pinnal-pedal reflex by rapidly scratching the leading edge of the pinna with a finger nail. If the ipsilateral leg starts stratching, then the test is positive. This test is positive in majority of Sarcoptes dogs, but negative with most other pruritic diseases, and is a rough tool, but if positive a parasite treatment trial is always indicated. Don't rule out Sarcoptes based on negative pinnal-pedal reflex. Check for concurrent otitis. As a general rule, if no infection to affect signs, atopy affects the pinna and opening most, while food allergy generally affects the horizontal and vertical canal more. If infection is present, this is no help. Crusting on edge of pinna is strongly suggestive of Sarcoptes.

Diagnostic Testing

Every patient gets cytology, skin scraping, and a parasite treatment trial.

- Perform cytology for bacteria and yeast. Major cause of pruritus complicates diagnosis of allergic disease. May be primary cause of pruritus in patients with hypothyroidism, etc.
- Skin scrape for Sarcoptes, Cheyletiella, Demodex. Negative scraping does not rule out either; however, if you get lucky and find mites, then no need to keep going with other diagnostic testing
- Parasite treatment trial is an essential part of a logical diagnostic plan for pruritus. The author prefers selamectin: every 2 weeks for three treatments. Alternatives include milbemycin at 2 mg/kg once weekly for 4 weeks or ivermectin 300 µg/kg once weekly for 4 weeks. Since any breed can be ivermectin sensitive, always titrate up to the full dose. Fipronil spray is useful for Cheyletiella, but is ***not*** effective at eliminating Sarcoptes, and therefore not useful for treatment trials. Lime sulfur dip is an excellent and safe miticide, that also happens to help with dermatophytosis, but is kind of smelly!
- Eight-week elimination diet trial followed by challenge feeding is the next step. Ideally a home-cooked diet of 50:50 pinto beans/yams, or you can add exotic meats such as kangaroo, ostrich, alligator, frog legs (check out www.exoticmeats.com). Rabbit/potato is my favorite novel protein diets. Recent study showed poor results with venison- or fish-based test diets; may be fine maintenance diets. Hydrolyzed protein diets are also a good choice, but not 100% either. Regardless of diet choice, the response to provocative challenge is the diagnostic part of the test!
- Food serology is awful at identifying the specific protein to which a patient is allergic; however, if positive for more than five ingredients, then food allergy is likely (and not just to those five ingredients)
- Antigen-specific intradermal testing or serology is not diagnostic to prove a patient has atopy, but is used to determine what allergens to put into immunotherapy
- Antibiotic or antifungal treatment trial. If unsure if infections are the reason for itch, or a consequence of a primary pruritic disease, then treat then re-evaluate. The author recommends cefpodoxime 5–10 mg/kg once daily or cephalexin 20 mg/kg BID for 30 days and ketoconazole 5 mg/kg once daily for 30 days. Combine with weekly antiseptic shampoo: Chlorhexidine, ketoconazole, miconazole, benzoyl peroxide. Focus on problem areas first; leave on 10 minutes
- Dermatophyte culture. Not a top five cause, but a good rule out if patient does not have one of the top five
- Biopsy is THE ESSENTIAL diagnostic test for any pruritic patient you can't place in the top five

THERAPY

In addition to identifying and managing primary causes, therapy should be instituted to provide temporary relief of clinical signs. Basic therapies include cooling, topical sprays/lotions, omega III fatty acids, antihistamines, corticosteroids, and cyclosporine. Cooling methods can modulate threshold and decrease pruritus. Try frequent cool water baths, an oscillating fan, menthol, or witch-hazel spray.

Omega III fatty acids and **antihistamines** may be beneficial in a mild pruritus, but are less likely to provide satisfactory results in severely affected patients. The dosage of EPA (eicosapentanoic acid) should be approximately 40 mg/kg/day. Alone fatty acids are not likely to substantially reduce pruritus; however, in combination with other therapies fatty acids can be beneficial, even reducing the amount of corticosteroid required. Do not use omega III fatty acids during food trials. Antihistamines are most useful for atopy, with minimal benefit if any in other pruritic diseases. Antihistamines are very safe, with minimal side-effects or contraindications. Failure to respond does not mean the patient wouldn't respond to a different antihistamine. Try several for a 2-week trial before abandoning hope.

Glucocorticoids

Glucocorticoids are the most effective method of providing immediate, substantial relief from pruritus. Evidence supports good to excellent response in 75% to 97% of atopic patients, using various study designs, drugs, and dosages. The goal of steroid therapy is temporary humane relief from refractory pruritus, but should never be a substitute for diagnosis and management of primary disease and secondary infections. Nor should steroids be first choice therapy for mildly affected patients. Overall steroids are safe and effective for short courses; however, even at low doses long-term glucocorticoids can have disastrous consequences. A recent prospective study (Torres SM JAVMA 2005; 227(2):239-243) showed that 23 of 127 dogs (18%) receiving long-term glucocorticoids for pruritic disorders had bacteriuria (vs. 0 of 94 dogs not on steroids). Bacteriuria may be "silent" as inflammation is suppressed and urine is dilute. Do not rely on sediment to screen for urinary tract infection (UTI). Recommend urine culture quarterly on all patients on prolonged course of glucocorticoids.

Our knowledge of the metabolism of the various synthetic corticosteroids in veterinary patients is not adequate. Most information on absorption, half-life, and relative potency is extrapolated from human literature. However, experience tells us that oral prednisone is a good first choice for dogs, especially when used in combination with antihistamine to reduce total steroid dose. Prescribe a high dose initially to break the itch-scratch cycle, then rapidly reduce to lowest alternate-day dosage that maintains relief. A common protocol is 0.5 mg/kg BID for 2 to 3 days, then once daily for 2 to 3 days, then twice daily. In general I prefer alternate-day dosing over once daily dosing, even if a higher dose must be given. For example, I'd rather give 20 mg every other day than 10 mg SID. How much is too much? Aim for a total dose in 12 months below the dog's weight (lbs) x 15. For example, an 80 lb Labrador should not exceed 1200 mg/year or sixty 20-mg tablets, or 600 Temaril-P (2 mg pred each). Methylprednisolone (Medrol) is slightly more potent than prednisolone. Multiply prednisone dose by 0.8 to get the methylprednisolone dosage (ie, 4 mg methylprednisolone = 5 mg prednisolone). Methylprednisolone is reported to have less polyuria/polydipsia (PU/PD) associated than prednisone or prednisolone. Dexamethasone and triamcinolone are good second choices due to longer half life and more pronounced long-term side-effects, such as thin skin and weak tendons. Recent evidence points to dexamethasone having a higher diabetogenic potential than prednisone. If a patient develop poor response to prednisone and if no other cause can be identified (pyoderma, Malassezia), try steroids from a different class. You may be able to return to prednisolone later.

Oral forms have rapid absorption and high bioavailability, so injectable steroids provide minimal benefit over oral forms unless owners cannot give pills (primarily an issue for cat owners). Injectable dexamethasone or prednisolone sodium succinate can be useful in emergency hypersensitivity situations, such as anaphylaxis or severe self-traumatizing pruritus. Depo-Medrol (methylprednisolone acetate) is used primarily in cats for management of eosinophilic granuloma complex or in atopic cats where other diagnostic and therapeutics have been exhausted. Significant disadvantages include not being able to tailor dose to patients needs or provide days off steroids. Depo-Medrol has no great value in managing dogs, other than convenience to owners at the expense of the dog's well-being.

Topical steroids, such as Genesis spray (0.015% aqueous triamcinolone), are useful for short-term relief of pruritic dermatitis when systemic steroids may not be indicated. Topicla steroids can alter adrenocortical access and will cause cutaneous thinning and milia if overused by clients. Recommend strict adherence to label recommendations. Steroid ointments have limited benefit except in the most focal pruritus

Microemulsified Cyclosporine (CsA) has multiple mechanisms of action: it inhibits T-cell activation, mast cell survival, response, histamine release, prostaglandin production, cytokine production, eosinophil migration, survival, and degranulation. Independent research demonstrates that CsA works! It really, really does! In a 13-dog comparison with prednisone therapy, CsA had equal efficacy: 10/13 (77%) responded with >50% reduction in pruritus and skin lesion scores. In a larger, 51-dog study, good to excellent response was reported in 78% of patients; 28/51 dogs continued therapy, with 10 on daily dose and 18 every other day or less. For dogs that discontinued therapy 12 of 51 (24%) stopped after achieving remission and did not relapse for an average of 12 months! Eleven of 51 (22%) stopped therapy prior to response because six owners felt there was no apparent benefit and five owners stopped for cost. Overall client satisfaction was great; 71% would use again, 17% maybe, and only 12% said no. No adverse events were reported in 78%.

Contraindications include neoplasia, demodicosis, dermatophytosis, and systemic fungal infection. Use with caution in hypertensive patients. The most common adverse reactions are vomiting, diarrhea, anorexia, and weight loss. Bacteriuria was reported in 8% of patients in one study (versus 18% with low-dose steroid). Less than 2% of patients experience cutaneous papillomatosis, gingival hyperplasia, hirsutism, periodontitis, cutaneous lymphomatosis (plaque) lesions that look like T-cell lymphoma, but go away when therapy is discontinued). At 5 mg/kg, side effects that are NOT SEEN include hepatotoxicity, nephrotoxicity, or myelotoxicity.

Cyclosporine does not replace diagnosis of primary cause for itch. Rule out parasites, infection, and food allergy prior to starting therapy. CsA is a really cool drug, but it doesn't kill fleas or Sarcoptes! For severely pruritic patients consider administering it along with prednisone. Since there is a lag period before CsA suppresses pruritus, prednisone can provide excellent relief while waiting. Aim for 5 mg/kg one time daily, but remember to decrease dose in obese patients because CsA is highly lipophilic. A human study showed increased serum levels correlated with increased obesity index. Ideally give on an empty stomach if at all possible (2 hours before meals), since giving with food decreases absorption. To mediate GI symptoms some dermatologists give with a meal for the first 10 to 14 days, and then switch to empty stomach plan. The vomiting appears to be dose dependent and temporary if you can get through the initial weeks. It can be combined with ketoconazole to decrease dose (and therefore cost). Ketoconazole competes with p450 metabolism of CsA resulting in higher serum levels. Ketoconazole given at a dose of 5–10 mg/kg reduces CsA dose by 50%

Recheck in 4 to 6 weeks. If the patient is doing brilliantly, then slowly decrease to every other day dosing. Drop one day per week with every new box of 15 capsules. For example, drop Tuesday. Next box, drop Tuesday and Thursday. Next box, drop Tuesday, Thursday, and Saturday. Next box, drop Tuesday, Thursday, Saturday, and Sunday (giving only Monday, Wednesday, and Friday). If the patient continues to do well, decrease to twice weekly or even once weekly. If pruritus returns at lower dose, go back to the last effective dose and try to decrease again in 3 months. If not achieving expected results, continue once daily dosing until maximal benefit then decrease to every other day. Seventy-five percent of patients that are clinically improved at 4 weeks will be able to decrease to every other day. Check for gingival hyperplasia (about 1 in 200 cases) and for profound proliferative change. Check for warts. For the one in four dogs that manifest GI disturbances you can stop for 3 to 4 days, restart with meals, restart at lower dosage, restart with dose divided BID, or give with metoclopramide, which is effective at suppressing vomiting but may affect hepatic metabolism resulting in higher than expected serum levels.

Allergen-Specific Immunotherapy

Allergen-specific immunotherapy (ASIT) provides a non-drug option for long-term treatment of atopy. While not directly antipruritic, ASIT modulates response to allergens and diminishes severity of hypersensitivity reactions. The precise mechanism of action is not known; however, the safety record is very good and there is excellent evidence for efficacy. Response rates as high as 70% have been reported for ASIT in veterinary patients. The earlier you start, the better. In human children, ASIT has been shown to alter or even stop progression of disease when used early. Evidence in dogs demonstrates best response when started earlier than fifth year of clinical signs. ASIT has a great safety record in dogs with only one reported case of anaphylaxis in a dog. In humans, severe life-threatening reactions can occur, but are almost always in asthmatics, not patients with atopic dermatitis. Facial edema, urticaria, lethargy, and anxious behaviors are reported in dogs but are uncommon. Increased pruritus and local injection site reactions are more common (up to 25% of cases).

METHICILLIN-RESISTANT STAPHYLOCOCCUS AND YOU

John C. Angus, DVM, Diplomate ACVD
Animal Dermatology Clinic, Pasadena, CA

Methicillin-resistant *Staphylococcus aureus* (MRSA) has already arrived as a major crisis in human healthcare. Both hospital-acquired and community-acquired strains are running rampant in various geographic regions, creating significant morbidity in at risk populations and major headaches for hospitals and the Centers for Disease Control (CDC). MRSA accounts for 30% to 40% of all hospital-acquired infections in humans, making MRSA the most prevalent nosocomial infection worldwide. In the US, 1.3% of the general population carries MRSA. More recently, methicillin-resistant Staphylococcal species (MRSS), including resistant *S. intermedius, S. schleferi, and S. hyicus,* have emerged as a growing concern in veterinary medicine. A recent survey at the 2005 ACVIM Forum in Baltimore demonstrated that 27 of 417 veterinarians (6.5%) carried MRSA in their nasal passages. Large animal practitioners were at highest risk (15.6% positive) compared with small animal practitioners (4.4% positive). Infections by MRSS have been reported in horses, dogs, cats, cattle, sheep, rabbits, chickens, and parrots. MRSS outbreaks in equine hospitals are of grave concern both for morbidity/mortality of patients as well as documented zoonotic spread to veterinarians and staff. Small animal cases are generally associated with "reverse zoonoses" or acquisition from an owner with a link to a hospital environment. However, recent reports for animal-to-animal and animal-to-human transmission with no links to hospitals have raised concerns of more widespread risk to human health from animal reservoirs.

WHAT IS METHICILLIN RESISTANCE?

First, we created penicillin to treat bacterial infections. Penicillin and other beta-lactam ring antibiotics work by inactivating penicillin binding proteins (PBPs), which are essential for building of the bacterial cell wall. All four native PBPs in Staphylococcus are inactivated by beta lactams, resulting in osmotic lysis of bacteria. Sneaky bacteria developed beta-lactamases that cleave the antibiotic ring conferring resistance to those bacteria that produce enough of these enzymes to prevent the penicillin from inactivating their PBPs. Clever humans then developed semi-synthetic penicillins to overcome beta-lactamase producing bacteria. Examples of early semi-synthetics include methicillin, oxacillin, and cloxacillin. Sneaky bacteria develop methicillin resistance almost immediately! Methicillin was introduced in 1959 and MRSA was first reported in 1961. Methicillin resistance results from the gene mecA, which codes for production of PBP2a, a non-native PBP that has very low affinity for beta-lactam antibiotics. If you produce PBP2a you have complete resistance to all beta-lactam antibiotics.

Short answer: MecA gene = methicillin resistant PBP = resistance to all beta-lactam antibiotics.

WHY SHOULD I CARE ABOUT MRSS?

MRSA adds a level of treatment challenge to any individual MRSS-positive veterinary patient. Traditional antibiotics don't work for MRSS pyodermas, urinary tract infections (UTIs), ear infections, pneumonia, or osteomyelitis. Moreover, there is a significant zoonotic concern for transmission from infected patients to the owner and veterinary healthcare providers. Veterinarians and staff may then become carriers and transmit to other patients. Additionally, creation of an animal reservoir for transmission to humans is of grave concern. Veterinarians risk CDC regulation of antibiotic usage if zoonotic MRSA is perceived to be a major threat to human population.

WHEN TO SUSPECT MRSS IN YOUR PATIENT?

The tricky thing about recognizing MRSS is that most strains are no more virulent or toxic than *S. intermedius*, just more resistant to treatment. Thus, clinical signs of MRSA are identical to regular old *S. intermedius* infections. MRSS is associated with pustular or follicular pyoderma, abscess, postoperative wound infection, or nosocomial IV catheter site infection. Orthopedic surgical implants are a common site for MRSA. Less commonly veterinary patients present with pneumonia, rhinitis, bacteremia/sepsis, septic arthritis, osteomyelitis, pyometra, or mastitis. Basically any suppurative infection can be MRSS.

Become suspicious if a suppurative infection with gram positive cocci responds poorly to empirically effective antibiotics (cephalosporins, Clavamox, fluoroquinolones). Be particularly suspicious if a person in the household has MRSA or a link to human healthcare.

HOW TO IDENTIFY MRSS?

First, perform cytology to confirm the presence of coccoid bacteria (Diff-Quik is fine). Submit culture swab. Be aware that most labs will call any coagulase-positive *Staphylococcus* isolated from a dog *S. intermedius*, even if it really is a different species of Staphylococcus. Most commercial labs do not perform tests necessary to differentiate *intermedius* from *aureus* or *schleferi*. This is should not be acceptable.

How do we know if our isolate is methicillin-resistant? Since methicillin is no longer commercially available in the US, it does not appear on the antibiotic susceptibility panel. Oxacillin is the standin for methicillin. The true test is if the animal carries the MecA gene or expresses PBP2a, but in general if an organism is reported as oxacillin-resistant, assume methicillin resistance. If oxacillin shows up as resistance, the lab is supposed to automatically report all beta-lactam agents as resistant even if in vitro testing shows susceptible. This means an "R" is populated next to all penicillins, synthetic penicillins, clavulanic acid-augmented penicillins, cephalosporins, carbapenems, and cephems. Unfortunately, some labs are slow to catch on to the presence of MRSA in veterinary patients, and still report "S" if in vitro susceptibility criteria are met. Personally I think it should be a criminal offense for veterinary laboratories to report susceptibility to these antibiotics in an oxacillin-resistant strain. **Bottom-line:** Do not use any beta-lactams for an oxacillin-resistant strain regardless of the lab report.

In addition to inconsistencies in laboratory reporting of MRSA, there are other disadvantages of using the antibiotic susceptibility profile for identification of MRSA. On the swab you submit, there may be mixed subpopulations co-existing that all look the same on the initial culture plate. Since the technician only selects one colony for susceptibility testing there is a definite opportunity for failure to identify the MRSA colony. Conversely, false positives do occur. A strain may be resistant to oxacillin in vitro but not be a carrier of the mecA gene, leading to inappropriate concern and management.

Additional testing can be performed to verify MRSA. Polymerase chain reaction (PCR) detection of mecA is the gold standard for identification and is available at some university microbiology laboratories. Additionally, Latex agglutination test can be performed to detect PBP2a. The CDC laboratory can analyze strains of MRSA to differentiate sub-types of MRSA (ie, hospital acquired versus community acquired). This is only desirable if there is a human in contact with the veterinary patient that has been infected by MRSA.

HOW TO TREAT MRSS?

Antibiotic treatment should be based on susceptibility testing and extended for 2 weeks beyond complete resolution. For surgical implant-associated infections, remove implants. Very few antibiotics are effective against the "hospital acquired strains." Basically, they are resistant to all beta-lactams, tetracycline, aminoglycosides, macrolides, chloramphenicol, and fluoroquinolones. Since 1996, vancomycin-resistant strains have been identified in humans—YIKES! "Community acquired strains" tend to be less scary on panels, but much scarier in concept since they could be lurking anywhere people gather. Typically the community acquired strains are resistant to only beta-lactams and erythromycin. Human cases are usually treated with vancomycin, linezolid, or daptomycin, or if susceptible, with trimethroprim/sulfa, gentamicin, or rifampicin.

For veterinary cases, regardless of what the lab report says, consider all strains resistant to penicillins, cephalosporins, cephems, ampicillin-sulbactam, amoxicillin-clavulanic acid, ticarcillin-clavulanic acid, piperacillin-tazobactam, and carbapenems. Veterinary isolates have variable resistance to gentamicin, rifampicin, cirprofloxacin (and other fluroquinolones), fusidic acid, co-trimaxazole, and tetracycline. More commonly they are susceptibility to amikacin, vancomycin, chloramphenicol, trimethroprim/sulfa, clindamycin, linezolid, and daptomycin. Generally avoid all beta-lactams and fluoroquinolones. Base treatment on susceptibility – trimethoprim/sulfa, chloramphenicol (55 mg/kg TID), clindamycin and aminoglycosides. Topical mupirocin ointment can be effective for some skin infections. Benzoyl peroxide wipes (Stridex Power Pads) can be useful for chin acne MRSA.

PREVENTION

Good hygiene is the single most important factor for prevention. Hand washing before and after every patient...and don't touch your nose. In a study at John Hopkins, doctors were much worse than nurses at washing their hands between patients (as few as 18%—YIKES). Extensive retraining, education, threats, rewards, and eventually circulation of photos of culture plates taken from hand prints at the staff cafeteria, resulted in compliance exceeding 90%. Environmental disinfection techniques should be regularly reviewed and reinforced in all clinical situations. *S. aureus* can remain viable for 17 hours in direct sunlight, 46 hours on clean glass surfaces, and up to 7 days on floors. I don't know about keyboards, telephones, and pens stuck in mouths, but probably longer than the period between the last time your colleague used it and you touched it....and then your nose. Men's ties were found to be excellent place to find MRSA in the human hospital setting. Trust no one.

Equine practices should establish screening and surveillance programs of patients and staff. Pets used in hospital and nursing home environments should be screened for nasal carriage. In humans, intranasal mupirocin is used to eliminate nasal carriage. This is impractical in dogs and cats. One asymptomatic carrier dog had MRSA successfully eliminated with oral doxycycline and rifampin. No acceptable options have been developed for horses.

SCARY STUDIES ABOUT METHICILLIN-RESISTANT STRAINS IN ANIMALS

- In horses, colonization by MRSS ranged from 2 to 130 cases per 1000 horses sampled across various farms, hospitals, and geographic regions. Foals in neonatal intensive care units are at high risk.
- In a survey of 7 North American veterinary teaching hospitals, 6 reported isolation of MRSA
    - 14% of all *S. aureus* isolates from animals were methicillin resistant
- A similar study in the UK found MRSA in 1.4% of all bacterial cultures.
- Documented zoonotic and reverse zoonotic cases:
    - Nurse involved in MRSA outbreak in nursing home was asymptomatic carrier, wasn't successfully treated until the same isolate was found and treated in her pet dog
    - Nasal cavity carriage of asymptomatic dog was implicated in recurrent MRSA infection in diabetic patient
    - Similar situation of woman with throat carriage of MRSA strain found in her dog
    - During an outbreak of MRSA in a geriatric nursing home, the resident cat became a carrier and the outbreak did not resolve until the cat was removed from the ward

  - In a veterinary clinic, five cases of postoperative MRSA infections were traced to the veterinarian as carrier of the same strain. Retrospective analysis estimated that strain was present in clinic for 2 years before detection
  - During outbreak of MRSA in a Veterinary Teaching Hospital Equine facility, 26 staff members were asymptomatically colonized. One veterinarian had a tattoo infection. Three personnel developed MRSA pyoderma after contact with a single sick foal
  - In a survey of a Veterinary Hospital in UK, MRSA was isolated from 14 of 78 staff members (18%), 4 of 45 dogs, and 3 of 30 environmental sites. Fluoroquinolone resistance was found in all isolates
- Retrospective survey of all staphylococcal isolates at the University of Pennsylvania (2003–2004)
  - 569 dogs/cats/birds/rabbits with positive culture for *Staphyloccoccus* sp.
    - 336 *S. intermedius*, 122 *S. schleiferi*, and 111 *S. aureus*
  - 145 of 569 had a methicillin-resistant strain (25.5%)!!!!!
    - 17% of *S. intermedius*, 40% of *S. Schleiferi*, 35% of *S. aureus* had methicillin resistance
  - 130 MR isolates were from dogs (0.6% of hospital population)
  - The oral antibiotic with the most reliable effect was chloramphenicol (95% sensitive), followed by trimethoprim-sulfa (68%)
  - Broad fluoroquinolone resistance was seen in the methicillin-resistant strains
    - 45% resistance in *S. intermedius*, 65% in *S. Schleferi*, 90% in *S. aureus*
  - Prior exposure to fluoroquinolone antibiotics is a risk factor for methicillin-resistant strains
  - Conclusions: Prevalence of *S. aureus* and *S. schleferi* is higher than previously thought. Prevalence of methicillin resistance is much higher than expected at VHUP. Fluoroquinolones are not a good choice for methicillin-resistant strains

Author Dan Morris states, "The ever increasing prevalence of 'human' strains in animal reservoirs suggests that perhaps it may be time for a paradigm shift in veterinary medicine...Veterinarians should no longer accept the one pathogen–one host concept."

TOP FIVE REASONS DOGS ITCH!

John C. Angus, DVM, Diplomate ACVD
Animal Dermatology Clinic, Pasadena, CA

Pruritus is defined as an unpleasant sensation that provokes the desire to scratch….or in our patients… rub, lick, scoot, chew, roll, shake or press against the coffee table. Pruritus is one of the most common reasons owners present their dog to the veterinarian. Short-term symptomatic management of most pruritus can be achieved with corticosteroids, but unfortunately corticosteroids don't usually resolve the cause of the itch, mask signs of ongoing or worsening disease, and are not generally suitable for long-term management of most conditions. As a result, the patient feels better, the course of therapy ends, and the itch returns, in some cases worse than before. Chronic recurring pruritus becomes a major source of frustration and misery for patient, owner, and veterinarian.

Ideally, for long-term management veterinarians should pursue the cause of the pruritus while providing short-term symptom relief. In order to pursue the cause, we need to have a good list of differential diagnoses. As an exercise I had my resident list as many distinct conditions which have pruritus as a clinical sign as she could; she came up with 43 diseases. The problem is that for a lot of these conditions there is no single pathognomonic clinical sign to differentiate this cause for pruritus from the other—basically there are lots of diseases that make dogs itch and they all look pretty much the same.

So armed with the knowledge that there are lots and lots of differential diagnoses for pruritus, how should one proceed? First, don't try to rule out 43 differentials the first visit. Second, realize that 95% to 98% of patients presenting for pruritus will have one of the top five causes, so you can ignore the other 38 differentials in the vast majority.

THE TOP FIVE

1. Atopy
2. Food allergy
3. Parasite hypersensitivity (Fleas, Sarcoptes, Cheyletiella, or Otodectes)
4. Malassezia dermatitis
5. Staphylococcal pyoderma

That's it! To make it even easier, Malassezia dermatitis and staphylococcal pyoderma are almost always complications of atopy, food allergy, or parasite hypersensitivity. So, pretty much you just need to do cytology to determine #4 and #5, treat them directly, and only worry about #1, #2, and #3.

DIAGNOSIS

History

None of the top five causes for pruritus can be definitively ruled in or out by history, but they can be ordered differently based on history

- **Age of onset?** If less than one year, think parasite hypersensitivity or Demodex. Between 1 and 4 years of age, anything is possible, but atopy is number one. Over 6 years of age, food allergy becomes more likely than atopy, but also start thinking hard about endocrinopathies.
- **Seasonality?** Definite seasonality is usually atopy or flea allergy dermatitis. Year-round pruritus doesn't eliminate atopy or flea allergy, but you get to pile on other differentials.
- **Higher risk for parasite exposure?** Recent adoptee in household? People or other animals in household itching?
- **Regular flea/tick control?**
- **Previous treatment?** Antibiotics/steroids/thyroid supplementation? Response? If highly steroid-responsive bump up atopy. If not steroid-responsive, bump down atopy and bump up food allergy, endocrinopathies, and unusual dermatoses such as T-cell lymphoma or erythema multiforme.

Breed

Not particularly useful, but can lead you astray, convincing you that a fox terrier has to be atopic when it really just has Sarcoptes (don't worry it will develop atopy later). Breed predisposition lists are over long, change based on breed popularity, change geographically, and change over time often enough to be rendered nearly meaningless. Any dog can be atopic, food allergic, acquire parasites, or become overpopulated with native Malassezia and/or Staphylococcus. Ignore breed and approach all itchy dogs the same.

Physical Examination

- **Characteristic lesions:** Atopy and food allergy look identical in the exam room, but two areas to look for atopy are the anterior flexural surface of elbow and the posterior carpus between pad and accessory carpal pad. Flea allergy tends to affect the back half of the dog worse, with classic signs of alopecia, erythema, papular dermatitis at dorsal tail head. Sarcoptes is most commonly associated with the pinna, elbows, flank; but not always. Never rule out Sarcoptes based on physical exam findings. Any dog that itches can be a Sarcoptes dog. Cheyletiella tends to have lots of dry scale on the dorsum.
- **Pinnal-pedal reflex:** Rapidly scratch the leading edge of the pinna with a finger nail. If the ipsilateral leg starts stratching, then positive. This reflex is positive in majority of sarcoptes dogs, but negative with most other pruritic diseases. A rough tool, but if positive a parasite treatment trial is always indicated. Don't rule out Sarcoptes based on negative pinnal-pedal reflex.
- **Concurrent otitis?** As a general rule, if no infection to affect signs, atopy affects the pinna and opening most, while food allergy generally affects the horizontal and vertical canal more. If infection present, this is of no help. Crusting on the edge of

pinna without canal involvement is strongly suggestive of Sarcoptes.

Diagnostic Testing

Every patient gets cytology, skin scraping, and a parasite treatment trial. Really, every patient!

- **Cytology**
    - Bacteria and Yeast. Major cause of pruritus complicates diagnosis of allergic disease. May be primary cause of pruritus in patients with hypothyroidism, etc.
    - Occasionally see dermatophyte endospores
- **Skin scrape**
    - Superficial – Sarcoptes and Cheyletiella. Negative skin scraping does not rule out either parasite; however, if you get lucky and find Sarcoptes then no need to keep going with other diagnostic testing until these mites are eliminated
    - Deep – Demodex
- **Parasite treatment trial**
    - Essential part of logical diagnostic plan for pruritus
    - Selamectin: every 2 weeks for 3 treatments
    - Milbemycin: 2 mg/kg once weekly for 4 weeks
    - Ivermectin 300 µg/kg once weekly for 4 weeks. Caution: Step up to full dose
    - Frontline (fipronil) is not effective at eliminating Sarcoptes
- **8-week elimination diet trial followed by challenge feeding**
    - Home-cooked: 50:50 pinto beans/yams. Can add exotic meat, such as kangaroo, ostrich, alligator, frog legs (www.exoticmeats.com)
    - Rabbit/potato is my favorite novel protein diets. Recent study showed poor results with venison or fish-based test diets; may be fine maintenance diets.
    - Hydrolyzed protein diets. Good choice, but not 100% either
    - Amino acid formulation currently being evaluated—may be the answer.
    - Provocative challenge is the diagnostic part of the test!
    - Food serology is lousy at identifying specific protein to which patient is allergic; however, if positive to more than five ingredients, then food allergy is more likely.
- **Antigen-specific intradermal testing or serology** are not diagnostic tests to prove a patient has atopy, but are used to determine what allergens to put into immunotherapy.
- **Antibiotic or Antifungal treatment trial** – Treat secondary infections then re-evaluate.
    - Cefpodoxime 5–10 mg/kg once daily or cephalexin 20 mg/kg BID for 30 days
    - Ketoconazole 5 mg/kg once daily for 30 days
    - Weekly antiseptic shampoo: chlorhexidine, ketoconazole, miconazole, benzoyl peroxide. Focus on problem areas first, leave on 10 minutes. Use conditioners, too
- **Dermatophyte culture** – Hey, not a top five, but a good rule out if patient is not one of the top five
- **Biopsy** – THE ESSENTIAL diagnostic test for any pruritic patient you can't place in the top five

Never underestimate the power of bacteria or yeast to produce an inhumane level of itch. Always treat secondary infections aggressively and you might find those intractable atopics are much, much easier to manage. Treat the occult *Sarcoptes* and you will have even better results.

SKIN DISEASES THAT MIMIC PYODERMA – A CASE-BASED DISCUSSION

John C. Angus, DVM, Diplomate ACVD
Animal Dermatology Clinic, Pasadena, CA

Pyoderma can be defined as a pyogenic, or pus-producing, bacterial infection of the skin. Pyoderma has a widely variable presentation, with clinical signs that include papules, pustules, epidermal collarettes, erythematous macules, purulent exudation, folliculitis, furunculosis, and cellulitis.

Pyoderma in its many forms is an exceedingly common dermatosis in dogs. Forty to 60% of patients seen at dermatology referral centers have bacterial dermatitis as a component of their disease process. Many cases referred to dermatologists have failed to respond to treatment for superficial pyoderma. There are many reasons for treatment failure: (1) owner compliance, (2) wrong antibiotic, (3) inadequate dose, interval, or duration of prescription, (4) antibiotic resistance, (5) failure to identify underlying primary disease, or (6) not really pyoderma.

This case-based discussion focuses on reason number 6: not really pyoderma. By the end of the article you should be able to answer these questions:

1) What are the top three differential diagnoses for papules centered of follicles (ie, folliculitis)?

a. ____________________

b. ____________________

c. ____________________

2) Top three differential diagnoses for pustules?

a. ____________________

b. ____________________

c. ____________________

3) Three more differentials when the top three strike out? You can come up with more than three!!!

a. ____________________

b. ____________________

c. ____________________

4) What four diagnostic tests should be performed on every suspected pyoderma case?

a. ____________________

b. ____________________

c. ____________________

d. ____________________

5) What one diagnostic test should be performed when pyoderma doesn't respond to therapy?

a. ____________________

CASES

Case #1: Sampson

9-month-old, male neutered, Bernese Mountain Dog
History of recurring "hot spots" on face. Problem started after he was neutered 6 weeks ago.
Physical exam findings: Large patch of alopecia with purulent exudate. Many "satellite" papules centered on hair follicles.

Notes:

Case #2: Texas

4-year-old, male intact, American Game Dog
History of progressive alopecia with crusts, erythema, and exudation. Not responsive to cephalexin
Physical exam finding: Generalized disease affecting all areas of haired skin

Notes:

Case #3: Lady

6-year-old, female spayed, Chinese Pug
History of atopy with seasonally recurrent inguinal pyoderma. This year getting worse instead of better with same treatment protocol.
Physical exam findings: Intense focal pruritus on ventral abdomen/inguinal region. Large pustules, erythematous macules, comedones

Notes:

Case #4: Shelby

5-year-old, female spayed, Rottweiller
Acute eruption of pustules on ventral abdomen, neck, and face

Notes:

Case #5: Brutus

5-year-old, male neutered, Great Pyrenees
History of atopy with seasonally recurrent bacterial folliculitis. This year getting worse instead of better with same treatment protocol
Physical exam findings: Alopecia, crust, erythematous macules over entire body

Notes:

GUIDELINES FOR PYODERMA SUSPECT

My general approach to patients presenting with clinical signs consistent with pyoderma is to use history and physical exam findings to rank likely differential diagnoses, perform three diagnostic tests in exam room, outline a treatment plan, and determine what my next step will be if Plan A fails.

History

- Is the patient pruritic? Variable pruritus suggests demodicosis, dermatophytosis, erythema multiforme, or other less common dermatoses. Pyoderma, Malassezia, atopy, food allergy, sarcoptes should all itch.
- Is this an itch that rashes or a rash that itches? Most pyoderma is secondary to atopy, food allergy, or parasite hypersensitivity; these all itch first then rash! If the patient rashes without pruritus or is only pruritic when pyoderma is active, consider hypothyroidism or hyperadrenocorticism
- Age of onset? Less than one year think parasite hypersensitivity or Demodex. Between 1 and 4 years of age, anything is possible, but atopy is number one. Over 6 years of age, food allergy becomes more likely than atopy, but also start thinking hard about endocrinopathies.
- Seasonality? Definite seasonality is usually atopy or flea allergy dermatitis. Year round, doesn't eliminate atopy or flea allergy, but you get to pile on other differentials.
- Higher risk for parasite exposure? Recent adoptee in household? People or other animals in household itching? If recently adopted or a new member to household, then DTM and treat for parasites.
- Regular flea/tick control? Use all your wiles to convince and cajole them into flea prevention.
- Previous treatment antibiotics/steroids/thyroid supplementation? Response? If highly steroid responsive bump up atopy. If not steroid responsive, bump down atopy and bump up food allergy, endocrinopathies, and unusual dermatoses such as T-cell lymphoma or erythema multiforme.

Physical Exam

- Distribution? Symmetrical distribution suggests auto-immune, endocrinopathy, or systemic disease. Asymmetrical or patchy suggests dermatophytosis, demodicosis, or pyoderma secondary to hypersensitivity disorder
- Haired skin only? Demodex, dermatophytosis only affect haired skin
- Nasal planum, lips, or mucocutaneous junctions? Autoimmune disease, erythema multiforme, or drug eruptions. Demodex and dermatophytes can be ruled out.
- Concurrent signs? Look for signs of Cushing's disease, hypothyroidism, or systemic illness. Look for erosions, ulcerations, or nodules that might push you to biopsy now.

Initial Diagnostic Testing

- Four essential tests for every patient: Cytology, skin scraping, DTM, and parasite treatment trial
- If no bacteria or yeast on initial evaluation recommend obtaining DTM during first visit
- If appropriate: thyroid panel, food trial, allergen-specific testing, screen for Cushing's
- If looks serious or fails to respond to your top differential: BIOPSY, BIOPSY, BIOPSY

Initial Therapy

- Systemic antibiotic for 3 to 6 weeks. First choice for routine pyoderma: Cefpodoxime (SID), second choice is cephalexin or Clavamox (BID). Fluoroquinolones only for gram-negative pyodermas or if culture says only choice. Don't recommend fluoroquinolones as first line for routine staphylococcal pyoderma due to emerging resistance
- Appropriate shampoo/conditioner: Chlorhexidine, benzoyl peroxide, ethyl lactate. May choose to combine with antiseborrheic ingredients
- Mupirocin ointment for localized pyoderma, such as chin furunculosis or fold pyoderma
- Aggressive flea control: "Golly, this probably isn't fleas, Mrs. Johnson, but I'd sure hate for Fluffy to get fleas while we are doing all these tests to figure out what is causing her problems." Or, "Ya know, I believe in controlling the things we can. I can't control ragweed, but I can control fleas."

Recheck Examination: 2 to 4 weeks while still on antibiotic

- Ask client to score pruritus, odor, appearance of skin (scale 1 to 10).
- Repeat cytology to verify if bacteria is resolving or if *Malassezia* is present
- If good response, treat for 1 to 2 weeks beyond "cure" and proceed to maintenance therapy
- If not improving, then evaluate all causes for treatment failure listed in introduction
  - Client compliance – verify and reinforce
  - Review antibiotic selection, dosage, and interval
  - Consider culture if you truly suspect resistance
  - Repeat skin scraping and DTM to be sure you didn't miss the common differentials
  - Any time dermatitis fails to respond to appropriate therapy for current diagnosis → biopsy biopsy biopsy. Could be T-cell lymphoma, pemphigus, or erythema multiforme.

Maintenance Therapy for Pyoderma if Good Response

- Treat primary underlying disease
- Antiseptic shampoo/conditioner every 1 to 2 weeks life long
- Immune modulation therapy: Staphage Lysate (Delmont Laboratories)

Answers:

1. Bacteria, demodex, dermatophyte
2. Bacteria, demodex, pemphigus foliaceus
3. Malassezia dermatitis, flea allergy dermatitis, sebaceous adenitis, pemphigus foliaceus, erythema multiforme, toxic epidermal necrolysis, epitheliotrophic T-cell lymphoma (mycosis fungoides), superficial migratory erythema (hepatocutaneous syndrome), calcinosis cutis, schnauzer comedone syndrome, follicular dysplasia, juvenile cellulitis (puppy strangles), bullous pemphigoid, dermatomyositis, vasculitis, systemic lupus erythematosus, contact dermatitis, sun-damage, eosinophilic furunculosis, Sarcoptes, Cheyletiella, trombiculiasis, hookworm dermatitis, pelodera dermatitis, canine distemper, leishmaniasis, pythiosis, zygomycoses
4. Skin cytology, skin scrape, DTM, and parasite treatment trial
5. Biopsy (bet you thought I was going to say culture – that's number 2 unless in high methicillin-resistant Staphylococcus area)

MANAGEMENT OF THE ATOPIC PATIENT

Jenise C. Daigle, DVM, Diplomate ACVD
Austin Veterinary Dermatology & Allergy
Austin, TX

THERAPY

Allergen avoidance, while logical, is time consuming but can be quite helpful. Measures taken to reduce allergens in the environment will help all allergic individuals. Dust covers on the pillows, mattresses, and pet beds help keep dust and dust mites under control. Wash bedding, throws, and blankets in hot water once a week. Room air cleaners with HEPA filters are great for small rooms such as bedrooms and are relatively inexpensive. Owners can dust and vacuum once a week, keeping the pet outdoors during the cleaning process. Indoor molds are present in basements, closets, laundry, garages, and bathrooms. Keep the affected animal away from these areas if possible. Outdoor molds are present in mowed grass, mulch, dried leaves, and low ground cover. Rinse the feet and wipe the hair coat down with a damp cloth to remove accumulated allergens. It is important to remember that percutaneous absorption of pollens plays a big factor in our atopic patients. Give your clients these guidelines at the beginning of immunotherapy and as part of your treatment program.

IMMUNOTHERAPY

The long-term time commitment needed from both the owner and the veterinarian for successful immunotherapy cannot be overemphasized. It is usually for the life of the animal. The owner must be willing to follow instructions accurately, be patient, and be able to communicate effectively with the veterinarian. The veterinarian must be able to recognize and treat other primary or secondary causes of pruritus (otitis, pyoderma, *Malassezia* dermatitis, and insect hypersensitivity) as they occur.

Owners should be advised of realistic expectations **before** allergy testing or immunotherapy. This form of therapy will not cure their dog of allergies. Nothing will. The goal of immunotherapy is reduction in pruritus and leveling off of the clinical signs during allergy season. The time observed to clinical response varies from 2 to 12 months, but I ask owners to be committed to one year. Owners should expect a 50% to 70% reduction in pruritus and dermatitis with this therapy alone. Adjunctive therapy will still be needed in most cases. Allergy shots are best administered at home and the owner should be comfortable with its administration. The owner should be trained to give the injections by your professional staff, be advised of common side effects to watch for, committed to giving the injections according to the protocol, and present the pet for regular follow-up visits. If the client is reluctant to give the shots, then of course they can be administered in the clinic.

Induction

There are several protocols used for immunotherapy in dogs and cats, none of which have been tested in a controlled study. By convention, most protocols include a two- or three-vial set starting with a either a 200 or 2000 pnu (protein nitrogen units) concentration building to a 20,000 pnu maintenance solution. The maximum number of antigens in a single vaccine is typically 15. During the induction period the injections are given every 2 to 3 days until the maintenance dose is reached.

When therapy is started, the owner is advised to watch for increased pruritus or exacerbation of dermatitis after an injection is given. This reaction occurs rarely, is dose related, and the owner must consult with the veterinarian. Should this happen, the dose is reduced to the previous amount where no pruritus was observed. Conversely, a reduction in pruritus followed by an increase before the next shot is due suggests that the injections should be given more frequently. Divide the dose and give the shots twice as often.

Symptomatic therapy is required in almost every case during the induction period and at various times of the year. Symptomatic therapy includes not only antipruritic medications (glucocorticoids, essential fatty acids, corticosteroids, antihistamines, topical shampoos and rinses) but also specific antimicrobial therapy. It is also VERY important to remember that allergy shots should be modified for each individual patient. It is very important to follow up with these patients and schedule routine follow-up examinations every 3 to 4 months or more frequent if necessary.

GLUCOCORTICOIDS

The principle of use of glucocorticoids for pruritus is to **use as infrequently as possible, as low a dose as possible, and NEVER let the treatment be worse than the disease.** Only short-acting glucocorticoids are recommended. The half-life must be shorter than the interval of dosing. Drugs that can be used on alternate-day basis include *prednisone, prednisone and methylprednisolone.* Methylprednisolone has a slightly longer half-life than prednisolone and 4 mg of methylprednisolone equals 5 mg of prednisolone. Methylprednisolone drug does not cause as much polydipsia. However, it is more expensive than prednisone or prednisolone.

Pruritic patients that are to receive glucocorticoid therapy for longer than 2 weeks should be given prednisone or prednisolone on alternate days or less often. Dosages needed to control pruritus at the outset of therapy may be higher than the dosage needed for maintenance. Alternate-day therapy does not eliminate all undesirable effects of glucocorticoids, but it does minimize adrenal suppression.

The use of injectable glucocorticoids is almost never advisable in the treatment of atopic patients. With repositol forms of glucocorticoids, suppression of the pituitary adrenal axis far outlasts the anti-inflammatory duration of the drug. Some owners will report that oral medication in the dog does not work as well as injectable. This problem can be corrected by increasing the initial dose of the oral drug or changing to a different oral glucocorticoid.

An anti-inflammatory induction dose of prednisone/prednisolone is 1-2 mg/kg/day for the dog. After the pruritus is controlled, the dosage is changed to an alternate day regimen and the dose is then decreased to the lowest possible level. There are a multitude of ways to decrease the dose from daily to every other day. One approach is to take the lowest daily dose that will control the symptoms and increase it by 50%. This dose is then given every other day. This dosage can then be adjusted down. The target dose for chronic maintenance therapy should be less than 0.5 mg/kg every other day.

Animals on chronic glucocorticoids supplementation **should be monitored** every three to four months with a bacterial culture and sensitivity of the urine, CBC and chemistry panel should be evaluated once or twice yearly.

Patients on chronic maintenance therapy should be acceptably itchy, not completely itch free!

STEROID-SPARING DRUGS

Antihistamines block the classic inflammatory effects of histamine. They may also directly inhibit or stimulate mast cell secretion, may change the number, activity or both of helper or suppressor T lymphocytes, and may activate other cells such as the eosinophil that alter mast cell function. There are *six different classes* of antihistamines (H1 blockers) and a great deal of individual variability in the response to antihistamines. It is worthwhile to try two or three different antihistamines, one from each class for two to three weeks each in evaluating the efficacy of antihistamine therapy. Antihistamines are also now classified as to first and second generation. First generation antihistamines may also activate muscarinic cholinergic, 5-hydroxytryptamine (serotonin) or alpha adrenergic receptors whereas few of the second-generation antihistamines have any of these properties.

The selectivity of the second-generation antihistamines reduces central nervous system toxicity. In addition, second generation antihistamines are not able to cross the tightly fused outer membranes of the endothelial cells lining the brain capillaries. Second generation antihistamines that have been tried in veterinary medicine include astemizole, loratadine, and certirizine. Astemizole is one of the most specific H1 receptor antagonists currently available. Sedation is uncommon, as this agent binds preferentially to peripheral H1 receptor **sites rather than to central H1 receptor sites.**

The major side effect of antihistamines is sedation; this may decrease after several days of treatment. Uncommonly excitation or tremors may be caused by high dosages. Increased efficacy may be expected when antihistamines are combined with fatty acid supplementation. Individual patients may develop antihistamine tachyphylaxis after a period of time. In these instances, a different antihistamine class should be evaluated.

Fatty acid nutraceuticals, when used appropriately, may modulate the formation of prostaglandins, thromboxanes and leukotrienes. In North America, n-3 fatty acids are used almost exclusively in allergy management. Diets rich in n-3 fatty acids can result in the incorporation of n-3 fatty acids into biological membranes, with a corresponding decrease in concentrations of n-6 fatty acids such as arachidonic acid. N-3 fatty acids are converted into a leukotriene B, prostaglandin E and thromboxane A that are less pro-inflammatory than the corresponding n-6 fatty acid isomers. In this regard, the ratio of n-6 to n-3 fatty acids in the diet is important. In one study, a ratio of 5:1 to 10:1 n-6:n-3 fatty acids resulted in a decrease of the inflammatory leukotriene B4 after 6 weeks in the plasma and 12 weeks in the skin. Most diets are probably much higher in n-6 to n-3 than this ideal. For control of signs of atopy in the dog, dosing of n-3 fatty acids at 180 mg of EPA/5 kg, used with a low-fat diet, was found to result in better control of the allergic symptoms. The n-3 fatty acids are contained in cold-water fish oils. Fish oil supplements, to be useful in allergy management, should contain at least 90 mg EPA/capsule.

Pentoxifylline is a phosphodiesterase inhibitor that has a number of anti-inflammatory effects: it decreases cytokine production (IL-1, IL-6 and TNF-α) and the expression of adhesion cell molecules thus decreases the accumulation of inflammatory cells at sites of allergen challenge (late phase cutaneous reaction at 4–6 hours). Pentoxifylline suppresses contact allergy by suppression of TNF-α which is considered an important mediator in delayed-type hypersensitivity. To date, its use does not seem to have decreased intradermal skin test reactivity. It has been tried with minimal success in canine atopics at 10 mg/kg TID.

Cyclosporine works by targeting the T lymphocytes binding immunophilin thus inhibiting calcineurin which is needed to produce inflammatory cytokines. This precise targeting of the T lymphocytes inhibits the production of the numerous cytokines driving the inflammatory reaction. Unlike systemic steroids that affect every cell in the body producing numerous unwanted effects, cyclosporine only affects inflammatory cells. The recommended dose for dogs is 5 mg/kg PO daily. Cyclosporine should be given for 30 days before assessing response. If pruritus has been reduced, you may be able to reduce to every other day for the maintenance dose. The drug should be given 2 hours before or after a meal to maximize its absorption. Unfortunately, 35% of dogs suffer gastrointestinal side effects including vomiting, loss of appetite, and diarrhea. These side effects usually resolve in 2 to 3 days. Metoclopramide can be administered if necessary to help control vomiting. Ketoconazole (5 to 10 mg/kg per day) can be administered concurrently to increase cyclosporine blood levels. In these patients, the dose of cyclosporine can be reduced (approximately half) or possibly tapered sooner than in patients not receiving the combination protocol. The addition of ketoconazole is especially useful in allergic patients with concurrent Malassezia dermatitis or otitis.

TOPICAL MANAGEMENT OF PRURITUS

Topical management can be used as *adjunctive therapy* in the management of the pruritic patient. In patients with generalized disease, topical therapy is applied by means of shampoo, rinse or conditioner. *These should always be applied with cool water.* Hot baths and high ambient temperature may potentiate pruritogenic stimuli. Shampooing mechanically removes surface debris, bacterial by-products and decreases percutaneous absorption of allergens. In addition, antipruritic medications can be effectively applied topically, in many instances.

Topical antipruritic products in the formulation of *gels, creams, lotions, sprays and ointments* will be helpful in patients with localized areas of pruritus. In selecting a product for topical therapy, one must consider the vehicle the drug is combined with. For acute eruptions, the nonocclusive, nonirritating lotion, spray or gel form should be used, whereas creams and ointments are best used in chronic lesions. Ear products with glucocorticoids can also be used on the skin.

Patient monitoring is essential. A variety of perpetuating factors (pyoderma, Malassezia, otitis, fleas, etc.) are likely to occur and must be controlled as soon as they occur. I schedule owners to return at two months (when they reach the maintenance dose), 5 months, 8 months and 1 year. If all is well at each of these visits, then follow ups are reduced to once to twice a year. If at the two month visit pruritus markedly escalates after a shot, then the dose is probably too high and should be reduced to the previous concentration where no pruritus was observed. If pruritus declines after a shot but increases before the next injection is due, then the shot needs to be given more often.

FOOD ALLERGY: HOW TO DIAGNOSE AND TREAT

Jenise C. Daigle, DVM, Diplomate ACVD
Austin Veterinary Dermatology & Allergy
Austin, TX

CLINICAL SIGNS

The clinical signs of food allergy can be quite variable. The clinical signs are going to be nonseasonal but seasonal peaks can occur if the patient has concurrent allergies, such as flea allergy dermatitis or atopic dermatitis. The signs are almost always cutaneous but concurrent gastrointestinal signs can be seen in some patients. While the great majority of dogs with food hypersensitivity manifest pruritus of the ears and feet, the distribution can also be extremely variable. Generalized pruritus may occur but some dogs will have the classic "ears and rear" involvement. In addition, pruritus localized to the ears may be the only symptom. Both primary and secondary skin lesions can be seen. These include erythematous papules, pustules (from secondary infection), seborrhea, angioedema/urticaria, excoriations, and traumatic alopecia. There is a subset of food-allergic dogs that present with non-pruritic, recurrent pyoderma. Other less common symptoms of food allergy include gastrointestinal signs, malaise, and seizures. Although many food-allergic dogs may present with initial symptoms at less than 6 months of age, food allergy can occur at any age. In general food allergy occurs in young and old dogs.

Nonseasonal pruritus is also the most common symptom of food allergy in cats. Often, pruritus is intense, and directed around the head and neck. However, generalized pruritus can occur. Food allergy has also been implicated as a cause of miliary dermatitis, eosinophilic granuloma complex, eosinophilic folliculitis/furunculosis, and self-inflicted alopecia in cats. Less common manifestations of food allergy in cats include gastrointestinal symptoms, angioedema/urticaria, and conjunctivitis. Gastrointestinal signs may include increased defecation frequency, soft feces, intermittent diarrhea, and flatulence.

DIAGNOSIS

Food allergy can mimic other dermatologic conditions, so it is important that a minimum dermatology database has been performed. Skin scrapings, both deep and superficial, Dermatophyte Test Medium (DTM) tests, and skin cytology should be performed to rule out other pruritic dermatosis and concurrent bacterial or *Malassezia* infections. With severe pruritus, I would also recommend empirical treatment for sarcoptic mange.

The most reliable method of diagnosing food allergy and the only one recommended is a hypoallergenic dietary trial. Antigens are available for intradermal allergy testing, and some of the serum ELISA or RAST allergy tests measure food antigens. The predictability of these tests or their correlation with provocative challenge is poor. **Neither skin testing nor serologic testing is a reliable diagnostic test for food allergy and should be avoided.**

The goal of the hypoallergenic diet is to clean the animal's system out of all previously fed foods with the ultimate goal being resolution of pruritus and/or dermatitis. Owners are reminded that the food trial is a TEST conducted at home. Our goal is to find out what foods should be avoided and then return to an appropriate commercially available diet. The idea is to do it once, do it right, and get the pet on a food it can eat that does not cause it problems. This *test* is accomplished by placing the animal on a controlled, limited ingredient diet for 8 to 12 weeks and monitoring the animal for signs of improvement.

After taking a thorough dietary history, a commercial single novel protein, and ideally novel carbohydrate, diet with very limited ingredients is selected as the initial diet. Alternatively if the client is willing, a home-cooked diet using a novel carbohydrate and protein source can also be used. Alternatively, there are now commercial diets that use hydrolyzed protein sources. The hydrolysis process alters the molecular weights of the proteins to the range of 5,000–12,200 daltons in the available veterinary formulations. In general the major food allergens (in people) are in the 12,000–70,000 dalton range. The hypothetical advantage of these diets is that if the molecular weight of the protein is small enough, it will not elicit an immunologic response in patients sensitive to the original protein.

A handout describing the restrictions of an elimination diet and a diet diary are given to the owner at the start of the food trial. The owner must be advised that substitutions, additions, snacks or treats (except fruits and veggies) are not permitted during the test period. **All flavored vitamin supplements, preventative medication, and fish oil supplements must be stopped or a nonflavored version substituted during the food trial.** All rawhide chew toys, pig ears, cat food, cat feces, and so forth must be placed out of reach. Outdoor pets should be confined during the course of the trial to prevent dietary indiscretions. Even the litter box must be made unattainable to the indiscriminate canine palate. It is also very important to *switch to non-chewable heartworm preventive!* A recent study at NCSU showed that once-a-month heartworm pill (containing soy and beef) is sufficient to keep a soy-allergic dog symptomatic.

The owner is advised to record the amount of the hypoallergenic diet fed/eaten, other food fed/eaten, level of pruritus, and character of stool on a daily basis. The diary is brought to each office visit for review by the clinician. Often information not volunteered by the owner (eg, animal boarded for a week during which time pruritus increased) is revealed in the diet diary. The owner is advised that their pet should not gain or lose weight while on the diet. The truth is that many animals whose pruritus has been treated with glucocorticoids have gained an excessive amount of weight and can stand to lose. The hypoallergenic dietary trial is an excellent time to help this along.

Scheduled follow-up evaluations (4 and 8 weeks) are key to assess the pet's response and to adjust the diet as deemed necessary. A realistic expectation is a 50% improvement in about 70% of the food allergic animals after 4 weeks on the elimination diet. Because some food-allergic pets have multiple simultaneous allergies, complete resolution of pruritus may not occur. If a superficial pyoderma or fleas are present, these conditions must be treated and eliminated before a fair evaluation of the elimination diet can be made. Evaluate the pet at 4 weeks and if pruritus/dermatitis persists, continue the diet for an additional 4 to 6 weeks.

The Dietary Challenge

The dietary trial is incomplete and a diagnosis of food allergy cannot be made without provocative challenge. This is accomplished by re-feeding the previously fed commercial pet food for 7 to 14 days. The diagnosis of food allergy is made when the signs reoccur upon feeding the commercial pet food, and is confirmed with resolution of clinical signs when the elimination diet is re-fed. Most often, signsy recur within a 24- to 48-hour period. The exception to this is the patient with recurrent pyoderma. Signs may not be observed for 7–10 days after initiating the challenge. Owners are asked to make a list of the ingredients in the commercial diet. A positive reaction (itching or dermatitis) on provocative exposure of this diet means that the animal is allergic to at least one of the items on the list.

A negative reaction with exposure to the previously fed base-diet does NOT rule out diet hypersensitivity, however. It is not unusual for the offending agent to be a treat (commercial or from the table), rawhide, or dietary supplement. Owners are advised that if their pet improves during the elimination period, but does not relapse on the commercial diet than this diet can be fed as the maintenance diet. However, if an owner desires to introduce another food or treat, it must be done with the same degree of careful, monitored exposure.

The final maintenance diet is determined by how the pet reacted on challenge. Of course the challenge list is not all-inclusive, so there may be some degree of trial and error involved with finding a final diet. In addition, it is always possible that the pet may develop new allergies in the future. However, this appears to be an infrequent occurrence in adult dogs.

FELINE ALOPECIA

Jenise C. Daigle, DVM, Diplomate ACVD
Austin Veterinary Dermatology & Allergy
Austin, TX

Feline alopecia is a common problem seen in everyday veterinary medicine. Alopecia is defined as loss of hair and may vary from partial to complete. Various patterns can occur such as focal, multifocal, diffuse, or symmetrical. Alopecia can be congenital or acquired. It can be a primary disorder, such as seen with endocrine disorders and follicular dysplasias, or secondary to trauma or inflammation (eg, dermatophytosis, demodex, allergies). It is important to formulate an organized history and diagnostic plan to limit potential differential diagnoses. An accurate diagnosis is imperative to successfully treat the alopecia.

DIAGNOSTICS

The most important factor before the workup is started is to determine if the alopecia is self-inflicted from over-grooming or if the hair has simply fallen out. This can be determined by placement of an Elizabethan collar or the use of a trichogram. If the hair regrows when the cat is placed in an Elizabethan collar then this confirms the cat is causing the alopecia. A **trichogram** is used to visualize the hair for evidence of pruritus (self-inflicted alopecia), dermatophytosis, endocrine alopecia, pigmentation defects, and growth phase.

Performing a Trichogram

1. Grasp individual hair with hemostatic forceps and pluck hair completely (approximately 20)
2. Lay hair on microscope slide (with mineral oil) with hair oriented in the same direction.
3. Examine hairs at low power for morphology, concentrating on hair bulb, shaft, and pigmentation.

The hairs are examined for integrity of the shaft, stage (anagen, catagen, or telogen), and pigmentation. If most of the hairs have been sheared off, this is likely the result of licking, as seen in cats that excessively groom. Hair breakage is also seen in coat-dilution alopecia and traction alopecia. Damage to the shaft can be seen with several uncommon conditions, but dermatophytosis is the most common cause. When a hair bulb is present, it is important to document whether the follicles are predominantly in anagen, telogen, or catagen. Anagen bulbs are round shaped, while telogen bulbs are often spear shaped. Predominance of telogen follicles can be indicative of endocrinopathies, nutritional disorders and metabolic diseases. This is not an exact science, however, and there is a great deal of breed variability.

Skin scrapings are an under utilized diagnostic tool in feline dermatology. Demodex mites are an important cause of alopecia. Deep skin scrapes are used to check for *Demodex cati*. Superficial skin scrapes are used to try to identify *Demodex gatoi*. *Demodex cati* is a follicular-dwelling mite and has a long slender tail, similar to canine *Demodex* mites. These mites are usually seen affecting a single pet in the household. Immunocompromising diseases such as hyperthyroidism, feline immunodeficiency virus (FIV), feline leukemia virus (FeLV), and underlying malignancy should be sought as the cause of demodicosis. Treatment for the cause of *Demodex* is more important than resolving the mites. Other parasitic causes of alopecia include chiggers, lice, *Notoedres cati*, and *Lynxacarus radovski* (cat fur mite). Diagnosis is usually straightforward by use of tape preparations, magnifying lens examination, and skin scrapings.

The diagnostic value of the **Wood's lamp** is limited to a screening test for *Microsporum canis*. Negative fluorescence does not rule out *M. canis* because fewer than 50% of these infections routinely fluoresce, and is not useful for the diagnosis of dermatophytosis caused by other organisms, including *M. gypseum* and *Trichophyton mentagrophytes*.

A Wood's lamp uses ultraviolet light filtered through a cobalt or nickel oxide to cause some fungi to glow green in a darkened room. A tryptophan metabolite is the fluorescing material, not the fungi or spores themselves. This metabolite is only seen when the fungus is growing on hair shafts; it is noticeably absent on scale, claws or material growing on a culture plate. Only *M. canis* fluoresces (also *M. distortum, M. adouinii* and *T. schoenleinii* in humans), and then only about 50% of the time. Whereas dermatophytes fluoresce an apple-green color, most scales and medications glow a more blue or violet hue. The examination must be performed in a darkened room. A complete examination of the skin surface will require almost 5 minutes. If positive hairs are present, these should be plucked and used for a DTM culture. Remember that fluorescence seen on surface scale, crusts or on claws is going to be false positive. Also, since the fluorescence is due to metabolites, not viable spores or fungi, a positive fluorescence might persist even in the face of successful systemic therapy.

Dermatophyte Test Medium (DTM) fungal cultures are used to isolate and identify dermatophyte organisms. Dermatophyte Test Medium is made with special ingredients that inhibit bacterial growth and turn red when dermatophytes grow.

Performing a DTM Culture

1. Select samples for culture. Wood's lamp can be used to help select contaminated hairs or scales.
2. Longer hairs should be clipped short and the area cleaned with alcohol to decrease contaminants. Inoculate material onto Dermatophyte Test Medium. I prefer the DermDuets by Bacti-lab.
3. If media are in capped vials, be sure the caps are not tightened.
4. Keep at room temperature but in darkened environment (some recommend incubating).
5. Check cultures daily for evidence of fungal growth and color change of DTM from amber to red. A daily log should be kept. Most dermatophytes grow as fluffy white colonies. Ignore any color change that occurs after 2 weeks.

6. Examine microscopically all fungal growth for purposes of identification.

A **biopsy** may provide useful information in identifying the cause of the alopecia. It is essential to provide a thorough history and description of physical findings to the pathologist. Select lesional skin and normal haired skin, and make certain that they are identified correctly. Histopathology can be helpful in differentiating congenital/hereditary, endocrine, and telogen defluxion from allergic causes. However, in mildly inflamed, trauma-induced alopecic skin, the results may appear as "normal."

A **complete blood count** with **serum chemistry profile** is sometimes useful as a diagnostic tool for feline alopecia. Most allergic causes will have changes in eosinophilic counts but are not diagnostic alone. If there is any clinical evidence of systemic illness associated with the alopecia, then laboratory blood work is indicated.

MISCELLANEOUS DISEASES

Bacterial folliculitis is an uncommon cause of feline alopecia. When severe traumatic alopecia is encountered, a concurrent bacterial overgrowth may ensue. Cytological examination and bacterial culture make a diagnosis. A positive response to antibacterial therapy can be a helpful diagnostic tool.

Feline allergies to fleas, inhaled allergens, and food allergens are among the most common causes of alopecia. A thorough history can help to differentiate self-inflicted alopecia from spontaneous alopecia. However, some cats are secretive groomers and the owner many not see the cat lick or pluck at the hairs. Many times there is a concurrent observation of increased hairballs because of the consumption of hair

When there is a sudden onset of alopecia and other causes of alopecia are ruled out, there are some uncommon circumstances to consider. Cats with urinary tract cystitis may suddenly lick exuberantly at the caudal abdominal region. Similar findings may also be seen in cats with impacted anal sacs. For both of these entities, the traumatic alopecia may extend to the caudal rear limbs, perianal region, and proximal aspect of the tail head.

There are several causes of alopecia related to hair cycle abnormalities. **Congenital hypotrichosis** and **alopecia universalis** (Sphinx cat) is usually a simple diagnosis to make and can be confirmed with histopathology.

SEBACEOUS ADENITIS

Clinically cats present with patchy alopecia, easily epilated hair, and various amounts of erythema, scales, follicular casts, and pruritus. The definitive diagnosis is obtained only with a skin biopsy. A pyogranulomatous infiltrate invades the sebaceous glands. In some cases there may be a systemic underlying disease. Cyclosporine at 5 mg/kg may be beneficial.

ALOPECIA AREATA (AA) AND PSEUDOPELADE

This rare disease is characterized by patchy (AA) to diffuse (Pseudopelade), usually noninflammatory non-pruritic alopecia. The diagnosis is made by biopsy and histopathology. In alopecia areata lymphocytes invade the bulbus and in pseudopelade the isthmic region. Alopecia areata may spontaneously regress. Therapy (immunosuppressive drugs) is usually not attempted or not effective.

MURAL LYMPHOCYTIC FOLLICULITIS

Mural lymphocytic folliculitis (sometimes associated to follicular mucinosis) has a variable clinical picture, from mild alopecic patches, to severe hair loss, erythema and variable amounts of pruritus. It is possible that this histological pattern reflects several different diseases: initial epitheliotropic lymphoma, drug reaction, sebaceous adenitis, dermatophytosis, demodicosis, pseudopelade, FIV infection, and even food allergy. The severity of the clinical picture and the prognosis depend on the etiology. Idiopathic forms of mural lymphocytic folliculitis have been described in middle aged to old cats. Therapy with steroids or cyclosporine may be beneficial. Prognosis is poor in severely affected animals.

HYPERADRENOCORTICISM

Hyperadrenocorticism is rare in cats. Clinical signs are similar to those of dogs, with the exception of polyuria and polydypsia, which are usually absent. Cutaneous lesions include patchy alopecia, easily epilated hair, dry seborrhea with dull hair, and in some cases increased fragility of the skin, which can be torn with minor traction.

PARANEOPLASTIC ALOPECIA

This is rarely seen in cats affected by pancreatic carcinoma or, less frequently, bile duct adenocarcinoma. These patients are usually systemically ill, anorexic, and may present with vomiting, diarrhea, lethargy, and weight loss. Results of biochemical blood analysis are usually within normal range. Radiographs and ultrasound usually fail to identify the tumor. The alopecia usually starts on the abdomen and legs. The hair is easily epilated and leaves a typically smooth shiny skin. In some cases there is pruritus and excessive licking, which exacerbates the alopecia. Secondary *Malassezia* infection may be seen in the clawbeds. Histologically, there is profound atrophy and miniaturization of hair follicles and mild hyperkeratotic hyperplasia of the epidermis, with occasionally a mild lymphocytic exocytosis. The prognosis is usually poor.

ATOPIC DERMATITIS — PATHOGENESIS, CLINICAL SIGNS, AND DIAGNOSIS

Douglas J. DeBoer, DVM, Diplomate ACVD
School of Veterinary Medicine
University of Wisconsin, Madison, WI

PATHOGENESIS OF ATOPIC DERMATITIS: THE OLD AND THE NEW

The pathogenesis of atopic dermatitis (AD) is complex, and incompletely understood even in humans. It is important to review what we know about the pathogenesis of AD in order to understand the logical diagnosis and treatment of this disease. Historically, the primary disease was considered to be an immunoglobulin E (IgE)-mediated hypersensitivity response to an inhaled allergen—"allergic inhalant dermatitis." The IgE produced would sensitize cutaneous mast cells; the mast cells degranulate upon further allergen exposure, with subsequent mediator release causing clinical signs. The "inhalant" nature of AD is in question, and it is possible that most allergen exposure may actually occur via percutaneous penetration. We now know that both the initial sensitization, and then the re-exposure to cause clinical signs, can occur via skin contact with the allergen.

Taking one step backwards, a major underlying immunologic abnormality in AD is an alteration in lymphocyte responses to antigens, such that there is a change from IgG production (the "normal" defense response— the one we hope to evoke with, for example, routine vaccination) to IgE production (the "allergy" response). When an animal's immune system encounters a foreign substance and an antibody response is evoked, whether the IgG or IgE response predominates is controlled by cytokines released by different subsets of helper T lymphocytes. If the IgE response predominates, this is an abnormal response, and sets the stage for allergy. Many things can potentially influence which response predominates. Modulating the IgG/IgE "balance" and returning it toward the "normal" IgG bias is the target of treatments such as allergen-specific immunotherapy.

Atopic dermatitis may not always be IgE-mediated; in fact, some authorities are even theorizing that the presence of IgE may merely be an "epiphenomenon" or marker of the true underlying immunologic disorder. In humans, about 70% to 80% of patients with AD have demonstrable allergen-specific IgE in serum or are positive on "allergy tests"; 20% to 30% do not and are NOT positive on these tests. Therefore, other mechanisms are clearly involved, at least in some patients. Some examples of other mechanisms that have been shown important in human AD, and are under investigation in animal allergy, include:

- Decreased epidermal barrier function, resulting in higher permeability of the skin to allergens and irritants;
- Epidermal cells that are more easily perturbed than those in nonallergic individuals; when disturbed, these cells release many different substances that enhance the inflammatory response;
- Reduced production of antimicrobial peptides by epidermal cells, leading to greater propensity for skin infections;
- Genetic factors—Many genetic polymorphisms have been identified in human atopic individuals, most of which have the effect of somehow augmenting the inflammatory response;
- The "hygiene hypothesis"—There is a much higher prevalence of allergy in areas of the world that are "cleaner" and have better medical care. It is thought that early exposure of children to microorganisms promotes a Th1 or nonallergic bias to the immune system, and that by limiting exposure to these organisms, this process does not occur.
- Self-trauma from scratching—This exposes molecules such as fibronectin that are binding sites for bacteria. It also releases autoallergens, and in some individuals there is actually an IgE response that develops against "self" allergens!

The allergens involved (and not involved) in AD include pollens, which are somewhat regional, although many pollen allergens are common throughout the US (eg, ragweed). House dust (one of the most common allergies in humans and certainly so in dogs) is a complex substance consisting of breakdown products from clothing, furniture, animal and human dander, molds, insect parts, and house dust mites. *Dermatophagoides pteronyssinus* and *D. farinae* are the most common house dust mites in the US. They contain the substances that are responsible for most dust allergy. Grain dust mites (also called "storage mites," eg, *Acarus, Tyrophagus, Lepidoglyphus*), which live and feed on stored grain products, may be important allergens. Some small animal patients are allergy test-positive to storage mites; this is currently an active field of investigation in veterinary allergy. Molds are found in all areas of the US in soil and decaying organic matter, damp basements, etc. There is controversy over the prevalence of mold allergy in dogs; in general, positive reactions to molds are less common in most allergy tests. Animals do not often appear to be allergic to other animal danders or to human dander. Other uncommon allergens include feathers, wool, tobacco, and furniture stuffings. Household insects may be important allergens in some areas. Substances not thought to be associated with AD in animals to date include lawn chemicals or fertilizers; synthetic rug fibers (nylon, acrylic); and most ornamental plants or houseplants.

There is strong evidence that secondary infections with staphylococcal bacteria and *Malassezia* yeast not only contribute to the discomfort experienced by people with AD, but also serve to enhance and maintain the allergic state. Although the concept of "staphylococcal hypersensitivity" appears less and less valid, it is clear that certain toxins secreted by staphylococcal bacteria can directly activate T lymphocytes, stimulate them to release pro-allergic cytokines, and perpetuate the allergic cascade. It has now been demonstrated that some dogs develop IgE-based hypersensitivity to yeast allergens. Obviously, if we have a situation where a dog is allergic to a component of the normal flora (which will always be replenished by nature), we have a serious long-term problem! Thus, aberrant reactions to normal skin organisms are frequently a part of AD. Infection alone may account for much of the discomfort in atopic pets. This becomes a critically important consideration when treating AD: identification and long term control of infections is an important part of management.

CLINICAL FEATURES OF ATOPIC DERMATITIS

History is an extremely important issue in all skin disease, but especially in diagnosing allergy, where there are some important historical clues that you may be dealing with an allergic pet. A prominent feature of atopic dermatitis is pruritus, initially unassociated with lesions. The pruritus almost always starts at 1 to 3 years of age, but the onset can be from 6 months to 6 years of age (or earlier?). It's rare for a dog to "become allergic" starting at age 7 or 8, ***except*** with food allergy, which can start at any age. The signs can be either seasonal or nonseasonal pruritus. If seasonal, over a few years, the "season" often lengthens such that it is year-round after 3 or 4 years. The pruritus may worsen from year to year. There may be changes in the degree of pruritus with changes in environment (eg, visits to friends, boarding, walks in the country).

Atopic dermatitis has strong breed predispositions in dogs (however, these are not absolute and subject to regional variation): it is more commonly seen in retrievers, terriers, Chinese Shar Peis, Boxers, and Dalmatians. If corticosteroids have been used for treatment, there is often a good response. Contrast this with diseases like food allergy and scabies, where there is often a poor response!

On physical examination, owners often say the dog itches "all over," but the worst places are classically any combination of the following: axilla, ventrum, lateral thorax, flanks; feet; and face/ears. There is typically alopecia, which is related to the pruritus and secondary complications, and can be remarkably symmetrical. Don't get confused and think of endocrine disease if a pruritic animal has symmetrical alopecia!

There is often no primary rash in atopic dermatitis. Early skin changes may be limited to just erythema. Most visible lesions are secondary to the pet's scratching, or to complicating diseases such as pyoderma, yeast dermatitis, or seborrhea. Excoriations from scratching may be seen. Secondary staphylococcal pyoderma is ***very*** common in allergic dogs, as manifested by a papular-pustular eruption, focal crusts, and epidermal collarettes. Secondary seborrheic disease is common in dogs, as is yeast overgrowth (*Malassezia* dermatitis).

Also very common is bilateral, chronic, recurrent otitis externa; in fact, bilateral itchy ears and intermittent ear infections is the major or *only* manifestation of AD in some dogs. Be sure to examine the concave surface of the pinnae: in this author's opinion, pinnal dermatitis is one of the hallmarks of AD in many patients. Recurrent "hot spots" can be a manifestation of atopic dermatitis. Some dogs and cats have ocular signs (conjunctivitis, lacrimation, rubbing at eyes), and a few have anal pruritus. Severely affected, chronic cases may have dramatic alopecia, hyperpigmentation, and lichenification. Respiratory signs are rare in dogs; cats may occasionally have "feline asthma," although so far no one has established a firm link between allergy and "asthma" in cats, as is clearly present in humans.

We know very little about AD in cats. In part, this is because "allergy testing" cats is more difficult and less well studied. The range of clinical signs seems broader than in dogs—cats can look very similar to dogs with AD, but there are also a variety of "feline skin syndromes" that have been linked to allergy, such as ventral symmetrical alopecia, miliary dermatitis, and eosinophilic granuloma.

INITIAL STEPS IN DIAGNOSIS OF ATOPIC DERMATITIS

Initially, AD is a diagnosis made clinically using the following three elements; all are *required* for a clinical diagnosis of AD:

- Compatible history
- Compatible clinical signs
- All other causes of pruritic dermatitis that can appear similar to AD have been ruled out.

The following diseases can especially mimic AD, and must be ruled out before you can make a clinical diagnosis: food allergy, flea allergy, mites (especially *Sarcoptes*, *Cheyletiella*), pruritic staphylococcal pyoderma due to some other cause, and primary yeast dermatitis. A typical diagnostic evaluation for a potentially atopic patient might therefore include (the order of tests depends somewhat on the case): good history and examination; skin scrapings to help rule out mites; skin cytology to find bacteria and yeast; flea control if fleas are seen or suspected; a hypoallergenic diet trial; treating pyoderma with antibiotics if it is suspected or present; treat for scabies; treat for yeast dermatitis if suspected or present. Diagnostic tests that are of limited value for atopic dermatitis include CBC and chemistries, which should be normal; a skin biopsy ("nonspecific" pattern of inflammation); and endocrine tests, which are normal.

It is very important to understand that atopic dermatitis is a *clinical diagnosis*—it is made using clinical observational skills and elimination of alternative differential diagnoses. AD is *not* diagnosed by use of an "allergy test." Allergy tests are useful only to *plan immunotherapy* once you are sure the patient is allergic.

ATOPIC DERMATITIS — IgE TESTS VERSUS ALLERGY TESTS

Douglas J. DeBoer, DVM, Diplomate ACVD
School of Veterinary Medicine
University of Wisconsin, Madison, WI

THE TRUTH ABOUT "ALLERGY TESTS"

The use of a confirmatory "allergy test" is commonly considered in the diagnosis of atopic dermatitis (AD). The first and most important thing to understand about "allergy testing" is that *no allergy test is perfect.* Allergy tests of different types have varying sensitivities and specificities, and ALL types have (to a greater or lesser extent) "false negatives" and "false positives." Therefore, allergy tests do not answer the question "is this pruritic patient allergic?" You cannot simply apply these tests to an itchy patient for the purpose of initially diagnosing allergic disease, because some patients with other itchy diseases will also be positive. A striking example is in canine scabies, where the presence of the scabies mite evokes an allergic response that may cross-react with other mites. Dogs with scabies can be highly positive on an allergy test to house dust mites, which could obviously lead to a rather serious error in diagnosis and treatment! Rather, allergy tests answer the question "in this patient for which I have already made a **firm** clinical diagnosis of AD, to which substances is he/she allergic?"

WHY AND WHEN TO TEST?

Why, then, consider performing an allergy test? The major reason to perform an allergy test of any type is NOT to diagnose the disease. *The reason is to allow the clinician to select allergens for use in allergen-specific immunotherapy…period!* Identifying the specific allergens to which a patient is sensitive may also enable the owner to pay closer attention to environmental factors that contribute to allergen exposure. In addition, some owners just plain want to know what their pet is allergic to! Consider, however, warning the owner of the fact that virtually never do we find a cat or dog is allergic to something that can be easily removed from the pet's environment.

When should you allergy test? Again, the first answer is "after you have already diagnosed allergy." That aside, there has been demonstration that the results of allergy testing can vary throughout the seasons. This is not true with every dog, in every situation; however if you have to choose a time to allergy test, the best time would be just after the pet has been exposed to every pollen and dust allergen for that season. In cold-weather areas, this means that allergy testing is best done in the late summer to fall, just after everything is done pollinating. In this case, the allergic response will be maximally "cranked up" to as many allergens as possible. As an example, a pollen-allergic pet may be highly symptomatic in May. But in May, it's been 10 to 11 months since that pet's immune system has been exposed to June and July pollens…so in theory, it's a *bad* time to test. These principles are in part theory, and will vary with climate and with individual pet. The age of the pet may also influence the decision to test. The author has tested many 1-year-old dogs with dramatically positive allergy tests. However, one also sometimes sees that young animals are negative on testing, but on repeat testing a year later they are highly positive. Thus, I always warn owners of very young animals that there may be a slightly increased chance that their pets will be negative.

PRINCIPLES OF ALLERGY TESTING

It is useful to examine the different principles on which allergy tests rely. Intradermal testing (IDT) is the method of choice for many specialists in veterinary dermatology and allergy. Intradermal testing has the advantage that it is a biological method that in some ways mimics the pathogenetic mechanism of the actual disease. A positive intradermal test requires not only presence of specific IgE antibody, but functional mast cells and microvascular response. With the notable exception of house dust mite allergen, intradermal testing appears to be relatively free from positive reactions in nonallergic dogs. It is also considered by some authorities to be more sensitive than serum-based methods. There are important drawbacks to IDT, the most obvious of which are its requirement for referral, and for discontinuation of treatment for weeks to months prior to the test. Being dependent on a biological system, results of IDT are subject to multiple other influences such as stress, concurrent disease, and presence of inflammatory skin lesions. Also, it is clear that some animals with strong clinical signs of AD are negative on IDT—again, it is not a perfect test.

In vitro testing methods (serum-based tests) are increasingly used both by specialists in veterinary allergy and by general practitioners. When done reliably and used properly, these tests are very valuable tools to use in formulating an immunotherapy prescription. These are "IgE Tests"—they measure *only* the amount of allergen-specific IgE present in the serum, and *not* whether this IgE is functioning to cause an allergic reaction in a pet. These tests do not prove cause and effect. In using serum-based tests, we are assuming that if allergen-specific IgE is present, it is capable of causing allergic signs, but this is not necessarily true! As is now hopefully clear, it is certain that *"there's more to allergy than just IgE."*

Generally, in vitro methods are convenient and accessible, but in some cases seem to lack specificity: with this test, the big problem may be "false positive" reactions. Some people call these "clinically insignificant true positives" because the animal may actually have serum IgE against one or more allergens, but without clinical significance. One strong advantage of the serum allergy tests are that they are unaffected, or at least less affected, by therapy. Antihistamine treatment will make an IDT completely negative, but has no effect on serum tests. With regard to corticosteroids, several laboratories recommend withdrawal of therapy for a time period before serum testing. This author believes that there is no clear evidence that use of medications such as corticosteroids meaningfully affect serum test results.

Although these serum-based methods have much to offer—especially when referral to a specialist is not possible—they must be used and interpreted cautiously.

WHICH TEST IS BEST?

It is useful to examine some of the components of different serum-based tests so that we might understand some of their advantages, disadvantages, and how they might be changing over the coming years.

- First, radioallergosorbent testing ("RAST") is no longer used; all tests performed today are based upon safer (nonradioactive) ELISA methodologies.
- Second, all assays depend on binding of serum antibodies from the patient with allergen. Whether this binding occurs on a solid substance, such as with conventional microplate ELISA or Western blot, versus in a liquid solution (solid-phase vs. liquid-phase assay), 'might' have some bearing on the results, as the allergen molecules might be more 'accessible' to the antibodies if they are floating in solution rather than bound to a solid. However, this benefit remains only a theoretical possibility in veterinary allergy diagnosis. This particular aspect of serum testing also seems less likely to influence its end result.
- Third, allergenic extracts can vary in their content substantially from manufacturer to manufacturer, and to a lesser degree from lot to lot. This could have profound implications on the results of a serum test, and perhaps even more impact on immunotherapy results. Although allergen standardization is progressing rapidly in the human field, allergenic extracts standardized for humans may or may not have any relevance to veterinary allergy, because the specific allergenic components of the extract (the major allergens) may differ between animals and humans. Standardization of veterinary allergen extracts is technologically possible, but the extreme cost of such an effort will limit our progress in this area.
- Finally, all serum-based assays depend on a detection reagent to specifically bind to and detect IgE, without detecting any other antibody class such as IgG or IgM. Monoclonal antibodies, polyclonal antibodies, and recombinant IgE-receptor fragments are the three detection reagents in use currently. In theory, this element of the test is one of the most critical in assuring sensitivity and specificity.

One general comment that can be made about *all* serum-based methodologies (and, indeed IDT as well) is that studies have concluded that these tests are *very poor choices* for diagnosing food allergy, and really should not be used. Even in humans, they are not very sensitive or specific. As another example, we know that food allergy does NOT always involve IgE-mediated processes. Therefore, even if we did have a perfect "IgE test" for food allergens (which we do not), this test would still be inaccurate for use in diagnosing food allergy.

So, which serum-based test method is best? In large part, that depends on what is meant by "best!" To elaborate:

- If we use "response to immunotherapy" as our criterion for evaluating success, among commercial serum testing companies, no method has been conclusively shown to be better than any other. The studies have simply not been done.
- If we use "correlation with IDT" as our criterion, no method has been shown superior; moreover, use of IDT as a "gold standard" can be questioned on theoretical grounds.
- If we use "technical performance" (issues such as repeatability, occurrence of false-positive reactions) the picture is slightly clearer. In a recent study, several "negative" (nonallergic) samples were sent in triplicate to five commercial serum allergy-testing laboratories in the US. There were substantial differences between laboratories in the number of positive reactions reported, and the repeatability of such reactions. This preliminary information suggests that quality control measures may vary substantially between commercial laboratories. This subject is deserving of additional study in the future.

Overall, if both are available, should one ideally use an IDT or a serum-based test? Again, neither test is perfect. With either IDT or serum-based testing, it is clear that nonallergic animals sometimes have positive test results, and that some allergic animals seem to have negative tests. In an ideal world, performing both tests probably gives the most information on a patient's relevant sensitivities, but cost considerations usually preclude this.

Point-of-care or in-clinic "screening tests" provide an alternative and interesting approach to allergy diagnosis. These rapid, inexpensive tests detect the presence of serum IgE directed against a mixture of common allergens, and a positive reaction in one screening test (E-Screen®, Heska) was recently highly correlated with positive reactions on IDT or more extensive serum-based panels. Hence, in theory they could be used to cost-effectively select which animals would be candidates for further testing. At this writing, such screening tests are only available in Europe.

MY LIST OF COMPLETELY UNSCIENTIFIC, UNFAIR, AND EMPIRICAL HINTS FOR INTERPRETING SERUM ALLERGY TESTS

The following list of hints is based on the author's clinical observations, impressions, and experience rather than scientifically proven fact, so use at your own risk!

- An IgE test is not a serum chemistry. There are no carefully established uniform standards and controls, or normal ranges. Don't take any value to be an undeniable truth. *You must always ask yourself "does this result make sense with the patient's clinical picture?"*

- Monosensitization (allergy to only one thing) exists commonly with house dust mite—some pets are dust mite sensitive only. It does NOT exist commonly with pollens. If you have only one or two pollens very positive, caution—these may not be significant, or at least they don't tell the whole story.
- Certain pollen extracts have a reputation for being "sticky" when used in ELISA assays, and seem to generate a larger number of "false positives." As you do more and more tests, you will get a feeling for this. Ask the lab if this might be going on.
- Mold spore allergy is not common. Most dogs positive on serum-based tests to molds are negative on a confirmatory IDT. This author believes that many mold-positives are not clinically significant.
- If you do have a dog with positive mold scores, make sure you've tried antifungal therapy. I believe in some cases, mold-positives are correlated with *Malassezia* hypersensitivity.
- If you do get a test result back that doesn't seem to make sense with the patient's clinical picture, don't just forge ahead with immunotherapy. It's expensive and long-term, and you want everything going for you if the owner's going to commit to it. If something doesn't seem to tell the whole story, make sure you've done a diet trial—could there be concurrent food allergy? It is very common that we will do an IDT to confirm suspicious or "borderline" ELISA test results—consider referral for an IDT.
- Use the expertise of your lab! They are generally very good at keeping all these things in mind, and providing appropriate immunotherapy recommendations, but if you question something, call their technical service advisors and ask.
- Invest a small amount of money in your own quality control. The next few pets you allergy test, take some extra serum and save it in the fridge. If you get a positive test, send the extra serum in under a fake pet's name. You should get *roughly* the same result. Don't expect it to be a perfect match. If the result is *dramatically* different, question the quality control standards of the lab.
- If you are really, really good at clinical diagnosis of AD, and you send serum samples in for testing, about 75% should be positive and 25% negative. If 100% are positive, you are probably dealing with a lab that is giving you some false positives.
- Don't charge an arm and a leg for allergy testing. Keep it cheap, so you can offer immunotherapy to as many clients as possible. This is not only good medicine, but good business!

ATOPIC DERMATITIS – DEVELOPING A MANAGEMENT PLAN

Douglas J. DeBoer, DVM, Diplomate ACVD
School of Veterinary Medicine
University of Wisconsin, Madison, WI

Atopic dermatitis (AD) is a complex, lifelong disease with many potential manifestations, and many possible modes of treatment. Treatment approaches must be individualized and flexible, combine several modes of therapy, and be aimed at both the primary disease and at secondary complications, to maximize success and client satisfaction. Within this "integrated approach," we see each of the potential therapy possibilities as "tools." Our goal with each patient is to find just the right combination of tools to provide lifelong therapy that is effective, affordable, convenient, and with as few adverse effects as possible.

Important elements of this approach include client counseling, the "pruritic threshold" concept, decreasing allergen load, decreasing pruritic load, use of medical treatments for short-term (and if necessary, longer-term) relief, and use allergen-specific immunotherapy if possible for potential long-term control.

CLIENT COUNSELING

Clients need to be told explicitly: *there is no cure for allergy!* Atopic dermatitis is a lifelong, controllable, but not curable disease. Owners should expect that things will not go perfectly—there will be relapses and secondary problems, and they should plan on higher-than-normal medical care costs over the patient's life. Also, because no one treatment is universally effective, it always takes time and experimentation to find the ideal treatment combination for the individual pet. Telling the client these facts may help to minimize the "clinic-hopping" that so often occurs with AD patients.

THE PRURITIC THRESHOLD CONCEPT

This general treatment concept holds that, in any given patient, a large variety of clinical factors are adding together to eventually push this animal over the "pruritic threshold" and result in severe clinical signs. The idea, then, is to identify and treat every possible factor that is contributing to the patient's discomfort. Factors to consider include:

- Seasonality of allergens – the management plan may be different during different parts of the year.
- Many animals have more than one type of allergy. Patients with AD sometimes have food allergy as well, and may be especially prone to flea allergy dermatitis if exposed.
- Secondary staphylococcal infections are common in AD, and contribute strongly to pruritus.
- Secondary yeast overgrowth is common in AD, and contribute as well.
- Secondary seborrhea is common, and not only augments pruritus, but facilitates infection and creates scaling, odor, and other unpleasantries for the owner.
- Secondary otitis externa is common – don't forget to specifically address the ears, if they are an issue.
- Any itchy disease is worse during hot, humid weather. Expect worsening in this case.

DECREASING ALLERGEN LOAD

Avoiding Pollen Allergens

Very few studies, even in people, address the success of pollen-avoidance measures. In part, this is because the important allergenic pollens are light and windborne, traveling many miles, and pollen avoidance is nearly impossible. Physician allergists generally recommend measures such as keeping windows closed (use air conditioning instead), minimizing outdoor activities during the morning hours when pollen counts tend to be higher, and avoiding freshly cut grass. With perhaps the exception of the last item, these measures are largely impractical in pets. Restriction of pollen-allergic pets to indoors may help, along with bathing or washing of the feet after outdoor exposure.

Avoiding Dust Mite Allergens

An entire industry is built on mite allergen reduction, from special mattress covers, to chemical house treatments, to cleaning services, to special vacuum cleaners and air filters. For severely dust mite-allergic pets, does environmental modification ("dust mite abatement") help? Dozens of studies in dust-allergic humans demonstrate that dust mite abatement measures can measurable reduce the amount of mite allergen in the household. However, the evidence for clinical effectiveness of these measures is limited and controversial, and just because you reduce the mite allergen doesn't mean the patient gets better!

In one canine study, the houses of mite-allergic dogs were treated with an acaricidal chemical (Acarosan Spray) every 4 to 6 weeks, until the results of a dust mite allergen test of the house were negative. During this time, the pets themselves received no treatment. About half of the patients in this study experienced benefit, but because the study was an uncontrolled trial, the results are a little difficult to interpret. This study is encouraging, but more work needs to be done before we can make a definitive recommendation to our clients. Importantly, to this author's knowledge, none of the products for environmental control sold in the US have been evaluated for their efficacy with atopic pets.

Avoiding Food Allergens

According to the literature, up to 13% of dogs with AD may also have concurrent food allergy. Therefore, as part of your exploration of the best management plan for each patient, it is always wise to try a hypoallergenic diet trial for at least 6 to 8 weeks to see if additional improvement results. No one diet or type of diet has been proven best for this purpose; either a novel protein or hydrolyzed protein diet should suffice. The most important concept here is that the diet trial needs to be strict. The recent wide availability of hypoallergenic dry and canned foods, treats, and chews make it much easier for clients to be compliant.

Preventing Allergen Penetration

Many humans with AD have decreased cutaneous barrier function. This leaky barrier allows easy passage of allergens and irritants through the epidermis. Strengthening this barrier function may thus help to reduce clinical signs. In humans, the primary method of accomplishing this is through application of emollient topical preparations, which is demonstrably effective. In pets, there are no published studies on topical products aimed at enhancing barrier function, but some companies are beginning to imply in their marketing literature that the product may have such an effect. We await careful studies before making any conclusion or recommendation.

It has been determined that canine skin cells, when cultured in vitro with certain nutrients, increase their synthesis of ceramides and lipids, which are components of the epidermal barrier. When these same nutrients are incorporated into dog food (Waltham Skin Support™), feeding this diet will measurably improve barrier function. The full clinical benefit of such "dietary therapy" has not been explored. Such diets are not miracles, but they may improve clinical signs in some patients.

DECREASING PRURITIC LOAD

Staphylococcal Pyoderma

Decreasing pruritic load begins with ensuring that good parasite control measures are in place. Following this, one MUST pay attention to the possible contribution of staphylococcal infection. Recurrent pruritic superficial staphylococcal pyoderma is extremely common in atopic dogs, and must be controlled as part of treatment. It is important, in each patient, to determine what portion of the overall itch is related to staphylococcal infection. This can only be evaluated by treatment with antibiotics alone for a period of time and monitoring the response. It is neither necessary nor desirable to use corticosteroids concurrently for this purpose, as their use may delay resolution of infection and will confound your ability to judge response to antibiotics. For animals where staphylococcal infection is an important and frequent source of discomfort, longer term treatment options include frequent chlorhexidine shampoos or conditioners, 2% mupirocin cream for localized areas, and intermittent use of oral antibiotics.

Yeast Overgrowth (*Malassezia* Dermatitis)

Dermatologists are increasingly recognizing the importance of "yeast overgrowth" (*Malassezia* dermatitis) as a contributing factor to atopic dermatitis, particularly in dogs. Always check for presence of yeast cytologically, and if present along with typical clinical signs (greasy or moist skin with severe pruritus that often does not respond to glucocorticoids), treat with an oral antifungal agent such as ketoconazole, fluconazole, or itraconazole (5–10 mg/kg once daily for 5–10 days). If the itch begins to decrease, it may be necessary to continue treatment for and additional 1 to 3 weeks to produce maximum relief; this is not always necessary and must be individualized per the patient's response. If the pet responds to an antifungal treatment trial, topical therapy may be used to treat and/or help prevent future recurrence. Maintenance treatment with 1% to 2% ketoconazole shampoo or cream, or ketoconazole-chlorhexidine/miconazole-chlorhexidine shampoos, rinses, or wipes is sometimes effective for prevention of recurrent episodes.

A new line of topical products (Douxo™) contains the ingredient phytosphingosine. This substance is a component of the epidermal barrier, inhibits bacterial growth, inhibits yeast, and has some interesting in vitro anti-inflammatory action. The author has found these products to be useful for some dogs with AD.

Atopic Otitis Externa

Atopic otitis externa (dogs or cats) is common as part of AD, and for some animals is a major manifestation of the disease, and deserves specific attention if present. Chronic inflammation of the ear canals results in oversecretion of cerumen, overgrowth of normal yeast and bacterial flora in the ears, and eventually ear infection. Cytology is mandatory to identify the state of the ears initially, and to plan for treatment of any infection that is present. Following resolution of bacterial infection and/or yeast overgrowth, many atopic pets benefit from periodic use of corticosteroid-only ear drops along with periodic cleaning with an ear product with residual antimicrobial action.

MEDICAL MANAGEMENT OF THE PRIMARY DISEASE

Antihistamines

Medical management of the AD should begin with the safest drugs to administer longer-term. Antihistamines may benefit 5% to 20% of pets, and they are always worth trying, though actually there is very little evidence that they are beneficial. Several should be tried for each patient. Good choices in dogs include diphenhydramine or hydroxyzine (2 mg/kg BID-TID); in cats, benefits have been seen with chlorpheniramine (2 mg/cat BID-TID) or fexofenadine (7.5–15 mg/cat, depending on size of cat, given BID). Combination with anti-inflammatory fatty acid supplements may provide additional benefit. There is no evidence that the newer, nonsedating antihistamine drugs now commonly used in human allergy have any additional benefit for animal use.

Anti-inflammatory Fatty Acid Supplementation

The "omega-3 and omega-6" anti-inflammatory fatty acids have been shown beneficial for some patients with AD. Most uncontrolled studies report 20% to 30% efficacy, and their effects seem to me relatively mild and of most benefit in early disease. The most important factor here is that the pet should receive a minimum of about 30 mg/kg/day of the anti-inflammatory fatty acids. There is no proven clinical effect of the "ratio" of these fatty acids in AD. Recently, pet food companies have increased the amount of fatty acids that are added to certain pet foods, including those intended for amelioration of skin or joint disease. In some cases, the amount of fatty acid present in these diets far exceeds "oral supplementation" levels. Therefore, if the pet eats one of these diets, supplementation with capsules or liquids is not necessary. Providing fatty acid therapy as part of the diet may be more cost-effective, more convenient, and assures that the pet receives the fatty acids consistently. Unfortunately, it is not always easy or possible to ascertain the amount of anti-inflammatory fatty acids present in a particular food by examination of the label. Hopefully, in the future pet food manufacturers will provide this information explicitly so that we can know which foods to recommend.

Even when fatty acid supplementation does not appear to benefit a patient on its own, it may be beneficial as part of combination therapy. Synergistic effects with both antihistamines and with corticosteroids have been demonstrated. As an example, if corticosteroids are the only thing that provides relief for a pet, or is the only treatment an owner can afford, concurrent fatty acid supplementation by capsule or through the pet food may help to decrease the total amount of steroid required to provide control.

Corticosteroids

Atopic dermatitis is generally quite responsive to corticosteroid drugs. They may be preferred for older animals that may not live to benefit from immunotherapy, or pets with highly seasonal disease. The chief disadvantages of longer-term use of corticosteroid drugs include development of steroid resistance or "tachyphylaxis," and adverse effects (of both annoying and medically-serious varieties). Oral prednisone or prednisolone (0.5–1 mg/kg/day, decreasing to every other day) is much preferred to other more potent drugs, or to injectable drugs, for reasons of longer-term safety. Concurrent use of the fatty acid supplements (as above) may decrease the required steroid dose. Animals receiving longer-term oral corticosteroids should have a urine culture performed twice annually to identify silent urinary tract infections. It is wise to check liver enzymes annually; elevation in serum alkaline phosphatase is expected and does not imply hepatotoxicity. Elevation in serum ALT or AST suggests progression of the effect and development of steroid hepatopathy.

Topical low-concentration (0.015%) triamcinolone spray is a relatively new corticosteroid formulation approved for canine use in the US (Genesis™, Virbac). In Europe, more recently a topical hydrocortisone aceponate spray has been approved (Cortavance™, Virbac). The latter corticosteroid is metabolized entirely in the skin, and is not absorbed into the systemic circulation, thus sparing the pituitary-adrenal axis. These solutions can be used for "trouble areas" of atopic dermatitis, such as the ventrum, feet, or anal area, or can be sprayed over broader areas of the body. The major advantage of these products is good (sometimes great) efficacy with lack of systemic corticosteroid side effects. They also may work even in patients where other corticosteroid formulations have failed. It is important not to over-apply the spray; use only enough to make the skin slightly damp without "runoff." The triamcinolone product is licensed for use for 1 month at a time; with prolonged continuous use, some animals may develop cutaneous atrophy or calcinosis cutis.

Cyclosporine A Modified (CsAM) and Other Calcineurin Inhibitors

The original cyclosporine A drug has been used for dozens of years as part of immunosuppressive therapy for organ transplant patients. The calcineurin inhibitors work by inhibiting production and action of cytokines, and through other mechanisms as well. More recent clinical trials of cyclosporine in dogs with AD demonstrate that this drug has efficacy equal to that of oral prednisone. Only the "modified" version of this drug (Atopica™, Neoral™, and generic forms available) should be used in dogs, as it is much more reliably absorbed. These preparations are the same drug, but microemulsified in a special vehicle to aid absorption. The starting dose is 5 mg/kg/day, which can be given as a single dose or divided into multiple doses. Ideally, CsAM should be given without food, as this will enhance absorption. Improvement occurs gradually, usually beginning after 1 to 2 weeks of administration and reaching maximum at 4 weeks. Thus, the initial trial should be 4 weeks. If the drug is effective, gradually reduce the dose over a period of several weeks to the minimum required for relief. Some patients will require the full starting dose long-term; others can be reduced to 50% or even 25% of the original dose for maintenance.

Perhaps 25% of patients will have some initial gastrointestinal discomfort from CsAM. In most cases, this will abate within a few weeks. Therapy with CsAM is remarkably free from long-term adverse effects. Patients on therapy do not seem to develop infections with greater frequency than other atopic animals. Gingival hyperplasia is a known adverse effect of longer-term, higher-dose CsAM therapy, but occurs only rarely at the doses typically necessary for AD. Protocols for combination of CsAM with ketoconazole for AD have not been developed. A major concern here would be potential for development of hepatotoxicity with long-term ketoconazole treatment. Concurrent administration of corticosteroids should be absolutely avoided for more than a few weeks. The combination of CsAM and corticosteroid has been associated with development of fatal opportunistic fungal infections.

Therapeutic monitoring (serum chemistries, blood counts, or CsA serum concentrations) is neither recommended nor necessary when using CsAM for AD patients. The drug works great in atopic cats as well, but is not approved for use in this species.

Cyclosporine is a large molecule, and is not readily absorbed through the epidermis. Other calcineurin inhibitors have been developed that are smaller, and active topically. Tacrolimus (Protopic™, Fujisawa) is the most commonly used of these topicals. Topical tacrolimus cream is very effective at controlling inflammation in human AD. Its use is limited in animals due to both the difficulties with using cream preparations on haired skin, and to its very high cost.

ALLERGEN-SPECIFIC IMMUNOTHERAPY

Allergen-specific immunotherapy (ASIT; formerly called “hyposensitization” or “desensitization”) is a treatment for atopic dermatitis in dogs and cats wherein extracts of allergens to which the patient is sensitive are injected, in gradually increasing amounts, to lessen or reverse the hypersensitivity state. Various theories as to how ASIT works have been advanced. The “blocking antibody theory” was popular for many years, but has been largely replaced by the “helper T lymphocyte subset” theory. This theory holds that subsets of T lymphocytes exist, one of which when stimulated evokes IgG production (Th1 response), and one of which evokes an IgE response (Th2 response). In an atopic state, the pro-allergic, Th2 response predominates instead of the more ‘normal’ or appropriate Th1 response. By administering large doses of the allergen extract, the balance between Th2 and Th1 is shifted back towards Th1. ASIT has a strong advantage of being nearly free of adverse effects in the great majority of dogs and cats, even with prolonged use. Disadvantages include the fact that it takes several months or more to begin working, that it does not always work, and that it may be relatively expensive.

Most effects of ASIT are thought to be allergen-specific, rather than nonspecific. Thus, accurate testing to identify the offending allergens in each patient is of paramount importance to successful immunotherapy. In particular, the clinician must strive to avoid ‘false positive’ allergy test results, which would result in including an allergen in the patient’s mixture that is not relevant to that individual’s disease.

Selection and formulation of an ASIT mixture is both an art and a science. Experimental observations that large doses of allergen evoke Th1 (IgG) responses and small doses of allergen evoke Th2 (IgE) responses suggest that there is some minimum, fairly large dose of each allergen necessary in a mixture to achieve benefit. Thus, many allergists limit the number of extracts used in each prescription to between 10 and 15 substances. When a large number of positive reactions are obtained with allergy testing, choosing the proper 10 to 15 substances can be based on the following: strength of the positive reaction; degree of possible exposure of the animal to the substance; consideration of patient characteristics; and botanical interrelationships of pollen allergen groups. Because proteolytic allergens present in mold extracts can degrade some pollen allergens, some allergists administer mold allergens by separate injection. Fortunately, commercial testing laboratories are knowledgeable about the details of formulating ASIT prescriptions and provide guidance.

The exact protocol and schedule for injections will vary according to the allergen preparation; generally, the extract manufacturer will provide an appropriate schedule. In some situation, particularly with very small animals or where the allergen mixture contains larger amounts of only a few allergens, the animal may not be able to tolerate the maximum specified dosage. In this case, the dosage may have to be reduced to between one half and one tenth of the normal full dose. Injections are given year-round, and the minimum initial trial period should be 12 months. As far as is known, concurrent treatments with antihistamines, fatty acid supplements, or low-dose glucocorticoids will not interfere with response. Many dermatologists now use CsAM initially with ASIT, though this can be questioned on theoretical grounds. Treatment is generally considered lifelong, though it is possible to attempt discontinuation after 2 to 3 years of injections if the animal has responded very well. If the owner stops giving the injections, then wishes to restart, the injection amount should be reduced and gradually increased again.

Expected response rate to immunotherapy is approximately 60% to 70% “good-to-excellent” response (defined as at least 50% improvement in clinical signs). Response can be seen as soon as 1 month, but more typically takes 3 to 6 months to occur, and the maximum response may take 1 year or longer. Adverse reactions to allergen immunotherapy include localized itch at the injection site and transient worsening for 12 to 24 hours after the injection (~10% of patients). Generalized anaphylaxis occurs in less than 1% of dogs and cats; such reactions are generally mild and further reaction can usually be prevented by pretreatment with an oral antihistamine 1 to 2 hours prior to each injection.

DISORDERS OF CORNIFICATION: TREATING THE SCALING BEAST

Douglas J. DeBoer, DVM, Diplomate ACVD
School of Veterinary Medicine
University of Wisconsin, Madison, WI

Seborrhea is a clinical syndrome that results from some transient or permanent disruption in the process of cornification. Seborrhea is a common secondary complication in many canine skin diseases; in this case, it's a clinical sign, not a diagnosis. Seborrhea also exists in several primary forms, where it is reasonable to make the diagnosis of "primary seborrhea." The owner complaint of an "odor to the coat that cannot be washed off" is often a good indication of the presence of seborrhea.

PATHOGENESIS OF SEBORRHEA

Cornification is an extremely complex process of division and differentiation of the skin's epidermal cells (keratinocytes) to form a tough, impermeable barrier to the external environment. This barrier functions to prevent fluid loss, prevent water movement into the body, provide mechanical protection against trauma and irritants, prevent ultraviolet (UV) light damage, prevent drug and toxin absorption, and many other functions. It consists of an orderly process of cell division, cell maturation, and cell desquamation. Disruptions in any step of this process result in increases in the number of cells being formed and desquamated, and abnormalities in the lipid content of the skin. Clinically, this is recognized as scaling, crusting, and an oily or waxy feel to the skin.

The pathogenesis of seborrhea is complex and not completely understood. Most studies have confirmed that there are at least three abnormalities that are found in the skin of ALL seborrheic dogs, whether primary or secondary:

- An increased mitotic rate of epidermal cells; the epidermal turnover time (time it takes a cell to traverse from the basal cell layer up to the surface and then be shed off) accelerates from 20 to 25 days normally to 3 to 5 days in seborrhea
- A change in the composition of skin surface lipids; normally, there are few or no free fatty acids in the skin lipid. In seborrhea, the percentage of free fatty acids increases, leading to irritation and inflammation of the skin. These substances are also degraded by skin microflora, leading to a musty or yeasty odor that reappears soon after bathing.
- A shift in bacterial flora in seborrheic skin. Aerobic bacterial counts (normally about 100 organisms/square cm) rise to more than 10,000/square cm. Additionally, there is a shift from nonpathogenic micrococci to coagulase-positive *Staphylococcus*. This accounts for the frequent bacterial pyodermas seen along with seborrhea.

CLASSIFICATION AND UNDERLYING ETIOLOGIES OF SEBORRHEA

Secondary seborrhea refers to seborrhea secondary to some definable underlying cause. Nearly any insult to a dog's skin, if it persists long enough, can result in seborrhea. *Most seborrhea seen in clinical practice is secondary.* Causes to consider include allergy (atopic dermatitis, food allergy, flea allergy); parasites (fleas, scabies, demodicosis, cheyletiellosis, lice); endocrinopathies (mostly hypothyroidism); metabolic disease (almost any type); nutritional problems (poor diet, malabsorption/maldigestion, zinc-responsive dermatosis); or neoplastic disease such as cutaneous T-cell lymphoma.

Primary seborrhea refers to seborrhea that occurs without a definable underlying cause; it is related to inherent defects in the epidermal cells themselves and may involve hereditary factors. This is most common and familiar in certain breeds, such as the cocker and springer spaniel, West Highland White terrier, Chinese Shar pei, and others.

In addition to primary versus secondary, some dermatologists like to classify the disease as oily versus dry seborrhea. In oily seborrhea, the skin has a waxy or greasy feel, the dog feels "dirty," odor is more prominent, and the scaling is off-white to yellow, moist, and adherent. In dry seborrhea, the odor is less, and the scaling is often finer and whiter, and comes off easier; this is analogous to "dandruff" in human beings. This is a fairly artificial separation, and really only useful for planning topical treatment.

DIAGNOSTIC EVALUATION OF SEBORRHEA

In diagnostic evaluation of seborrhea, the most important determination to make in an animal—the initial aim—*is to determine whether the seborrhea is primary or secondary.* Initial diagnostic workup consists of assuming the seborrhea is secondary, then making a list of all reasonable differential diagnoses as to underlying causes, and ruling them out one by one. Such evaluation may include, depending on the clinical signs, skin scrapings, empirical treatment for mites, fungal culture, allergy evaluation, a hypoallergenic diet trial, thyroid evaluation, and evaluation for underlying systemic disease (complete blood test [CBC], chemistries, urinalysis). Animals with any evidence of concurrent gastrointestinal disease should be evaluated for digestive problems. While doing these initial evaluations, you should at the same time be treating the pet for secondary complications such as staphylococcal pyoderma or yeast dermatitis, which are nearly always present.

Skin biopsy with conventional histopathology is an extremely valuable and underused diagnostic technique in seborrhea. It can give indications as to whether seborrhea appears to be primary or secondary, and may also give clues to the underlying disease in secondary seborrhea. In addition, it is the ONLY test that will definitively diagnose some of the rarer, defined syndromes that create severe seborrhea such as mycosis fungoides (cutaneous lymphoma). Punch skin biopsies (6 mm) should be taken of several representative areas and ideally sent to a veterinary dermatopathologist. It is important to clear up secondary infections BEFORE biopsying a seborrheic patient. The infections themselves evoke such an inflammatory response in the skin, that they may "overwhelm" the skin and make it impossible for a pathologist to observe the changes that would be associated with, for example, primary seborrhea.

TREATMENT OF SEBORRHEA

In all cases of secondary seborrhea, the best treatment is obviously aimed at the primary underlying cause. However, adjunct symptomatic treatment of the seborrhea with topical shampoo products can hasten resolution. The aims of treatment are to (1) slow the epidermal turnover time towards normal (reduce the scaling at its source); (2) normalize the "oiliness" of the coat (decrease or supplement it, as necessary); (3) control seborrheic odor; and (4) remove excessive scaling and crusts from the coat. Consideration of these principles in relation to the patient will help you choose the ideal shampoo regimen.

The "classical" ingredients in antiseborrheic shampoos are now being supplanted, or in some cases replaced, by newer ingredients with purportedly (though not always conclusively proven) equivalent or better results. Generally, the actions of the major ingredients are as follows:

- **Tar:** Acts as an antimitotic to "poison" the epidermal cells and decrease their mitotic rate, thus stopping cell production at its source. Tar is also quite drying. It is slowly disappearing from shampoos, in part due to problems with standardization and in part due to (probably unfounded) concerns as to possible carcinogenicity.
- **Sulfur:** Also helps to normalize epidermal turnover time and the cornification process ("keratoplastic" action). Has some antipruritic, antimicrobial, and parasiticidal activity.
- **Salicylic Acid:** Helps to "break up" or dissolve the adherent scaling and crusting ("keratolytic" action), so it can be washed away by the detergent and water.
- **Benzoyl Peroxide:** Breaks up scaling and crusting but is very drying and can be irritating to some animals; excellent antibacterial activity; bleaches fabrics and haircoats!
- **Phytosphingosine:** A novel ingredient that is a component of the intercellular matrix of skin. It has antimicrobial, anti-inflammatory, and barrier-enhancing properties.
- **Antimicrobial Ingredients:** Most of the above ingredients have some antimicrobial action. In addition, some shampoos may contain specific compounds such as ketoconazole, chlorhexidine, piroxone, or others. These are aimed at reducing the count of the bacterial and/or yeast populations on seborrheic skin to reduce the incidence of secondary infections.
- **Humectant Ingredients:** Many antiseborrheic shampoos or post-shampoo sprays or rinses contain humectants, various oily or non-oily moisturizers to restore moisture to a dry coat.

The important general principles of antiseborrheic shampooing are to use the shampoos frequently (twice weekly at first), and to allow 10 to 15 minutes of contact time of the lather with the skin to allow for penetration.

The evidence for usefulness of fatty acid supplements ("coat conditioners" or supplementing diet with vegetable and animal fat) in canine seborrhea is thin. Some dermatologists recommend them, but it is generally uncommon for a fatty acid supplement alone to do much for seborrhea. It is, however, wise to insure that the pet is eating a high-quality diet and not being fed a marginally nutritious ration of table scraps or cheap dog food.

Primary seborrhea is a controllable, but not curable, disease. It is wisest to sit down with the client and explain the prognosis and the likely necessity of lifelong treatment. The mainstay of treatment for most dogs with primary seborrhea is topical therapy with antiseborrheic shampoos. Controlling secondary infections is always a consideration in these pets. Different patients tend either to get staphylococcus overgrowth, yeast overgrowth, or both, the same thing over and over again. Thus, it is important to identify which of these is a problem for the individual dog so that shampoo therapy can be tailored to the pet's needs.

Some dermatologists (including the author) believe that some dogs with primary seborrhea benefit from vitamin A supplementation of their diet. This disease is not a dietary deficiency, but vitamin A in high doses has pharmacologic actions including modification of the cornification process. The "right" dose has not been established, but a reasonable guideline is one 8,000 IU capsule (the common "standard" size in the US is 8,000 IU Vitamin A) per 5 kg of body weight per day.

Primary seborrhea is often accompanied by severe seborrheic otitis externa. The otitis starts as a ceruminous otitis, but if left alone often progresses to bacterial or yeast otitis, because the cerumen is "food" for the normal ear bacterial and yeast flora. Appropriate routine ear cleanings, using a cleaner that contains antimicrobial ingredient(s), are indicated to keep numbers of bacteria and yeast down. The owner should learn to clean the ears at home and do this routinely once weekly to every other week. If the otitis includes a substantial inflammatory component in the absence of infection, many pets will benefit by routine (1–2x weekly) use of a corticosteroid-only ear drop. Corticosteroids not only suppress inflammation, but also inhibit cerumen production. Some cocker spaniels with long-term inflammatory ear disease from any cause, including primary seborrhea, develop severe proliferative otitis. This can literally progress until the external ear canal is completely closed off and ossified. This makes treatment difficult to impossible. This is a preventable situation! Warn owners of seborrheic spaniels early on to avoid future problems!

Seborrhea is uncommon in cats, especially when compared with dogs. Principal causes to consider include a parasitism like lice, mites, or fleas. Allergic cats don't often get secondary seborrhea like dogs do. Primary seborrhea is not recognized in cats. Seborrhea appearing in a middle-aged to older cat, especially if moderate to severe, is a danger sign! It often indicates a potentially severe underlying metabolic disease, such as hyperthyroidism or diabetes mellitus. Always test for an internal medical problem in a seborrheic older cat!

Several unusual seborrheic syndromes exist, such as *granulomatous sebaceous adenitis* (GSA). This is an uncommon syndrome that can be seen in any breed, but is mostly reported in Viszlas, Akitas, Samoyeds, and Standard poodles of any age or sex. It is clearly a hereditary disease in Standard poodles. In this disease, the sebaceous glands appear to be destroyed by the dog's own inflammatory cells. The clinical signs are somewhat variable, but usually include a progressive, nonresponsive seborrhea with alopecia; there may be annular or circular areas of hair loss and scaling. This disease is diagnosed easily, but *only* by skin biopsy, and is a great example of why you should always do a skin biopsy in a severe seborrheic skin disease! Topical antiseborrheic shampoos and humectants are slightly helpful, but the prognosis is poor. Systemic cyclosporine A modified (5 mg/kg/day, orally) works well for many dogs with GSA, but is expensive.

Seborrhea is a complex, multifactorial disease, but consideration of the common pathogenetic features of the condition and careful diagnostic evaluation can lead to treatment strategies that will provide substantial lifelong benefit, even in primary seborrhea.

ON THE HORIZON: METHICILLIN-RESISTANT STAPHYLOCOCCI

Douglas J. DeBoer, DVM, Diplomate ACVD
School of Veterinary Medicine
University of Wisconsin, Madison, WI

Coming soon to your town...the "flesh-eating bacteria" that no antibiotic will stop! News stories on emergence of resistance in staphylococci and other organisms are appearing in the public press with increasing frequency, sometimes with a rather alarming tone that prompts clients to question your therapeutic strategy more closely. What is really happening on this scene?

ALTERNATE STAPHYLOCOCCAL SPECIES

Our understanding over the past 30 years has always been that nearly 100% of cases of canine staphylococcal pyoderma are caused by the "canine strain" of staph, that is, *Staphylococcus intermedius*. Usually, staphylococcal organisms will stay on their "preferred host." *S. intermedius* is not transmitted to human beings under usual circumstances; human *S. intermedius* infections have mostly been limited to unusual situations and things like infected dog bite wounds.

Recently, increasing attention has been paid to the fact that the "human strain" of staph, *Staphylococcus aureus*, has been occasionally seen as a cause of canine infection. In this case, the organism probably was transmitted from the owner to the pet. Many human beings transiently or periodically harbor *S. aureus* in the nasal passages without clinical consequence. When we do see transmission, there is often "something odd" about the situation. For example, this may occur not as a garden-variety superficial staphylococcal pyoderma, but rather in something like purulent otitis media. Or, it may occur when there has been excessive use of multiple antibiotics, subtherapeutic dosing of antibiotics, or an immunocompromised host. It may be more common for a dog to become infected with *S. aureus* when one of the humans in the household is a healthcare worker.

The practical significance of canine *S. aureus* infections depends on the situation. Most strains of *S. aureus* are still quite susceptible to routine antibiotics such as the cephalosporins, and are easily treated, so this finding is of little consequence. However, if the household includes immunosuppressed individuals, or those who are to undergo surgery soon, the owner should be made aware of the fact that the pet may represent a "reservoir" of staph organisms that could be transmitted to these compromised family members, until the infection is fully treated.

Staphylococcus schleiferi is a newly identified coagulase-positive staphylococcus in dogs. The organism itself is not new, merely our recognition that this different type sometimes infects dogs. So far, there has been no strong or consistent association between *S. schleiferi* and disease severity, recurrence, or antibiotic susceptibility. At this point, there's not much practical significance to this finding.

Remember, also, that most laboratories do not report the species of *Staphylococcus* on a culture—they simply report "coagulase-positive staph," which means the organism could be any of these species, and so in practical terms, you may never know if you were indeed dealing with an *aureus*! Separating out the species involves extra time and expense, and is usually unnecessary, though you can order this procedure from the lab if you desire. This author believes it is prudent in any case where the organism appears methicillin-resistant (see discussion below) to order a staph speciation. The main reason is to detect the presence of a methicillin-resistant *S. aureus*, which is potentially a human health hazard.

EMERGENCE OF METHICILLIN-RESISTANT STAPHYLOCOCCI

There has been a recent increase in reports of multi-drug resistant staphylococcal strains. These strains include the *intermedius, aureus,* and *schleiferi* varieties. In particular, the methicillin-resistant staphylococci (MRS) are of concern.

Methicillin is a laboratory antibiotic, used to test general susceptibility of the bacterium to the "penicillinase-resistant penicillin" group of antibiotics. Clinically-used antibiotics in this group include oxacillin, dicloxacillin, and amoxicillin/clavulanic acid; methicillin itself is not used on patients. If the organism is methicillin-resistant in the laboratory, it will be *clinically resistant to all penicillins and cephalosporins*. These MRS are still uncommon in many areas of the US, but in some areas (notably the northeast urban areas) they may approach 30% of isolates obtained from dogs with pyoderma.

What is the significance of these organisms? First, if you treat a dog with staph pyoderma with a beta-lactam antibiotic (cephalosporin or penicillin) and there is no response, culture and susceptibility testing is now mandatory. Fortunately, most veterinary strains of MRS are still susceptible to routine antibiotics such as trimethoprim-sulfa, clindamycin, or a fluoroquinolone. If you have such a patient in your hospital, you need not have the dog under full isolation procedures, but you should isolate the patient to the extent you can, and minimize traffic from this patient to other dogs in the clinic, especially the surgery and critical care areas.

Second, if you do identify an MRS organism, especially if it appears to be very resistant, *you should order a staph speciation*. If the organism turns out to be a highly resistant methicillin-resistant, human-origin *Staphylococcus aureus* (MRSA), the owner should be notified of this fact so they can discuss the situation with their own health care provider. This patient is a potential human health hazard and should be considered so until the infection is fully treated.

Third, the emergence of MRS in the veterinary world suggests that we must redouble our efforts to use antibiotics wisely and judiciously, and reconsider all efforts to use alternate non-antibiotic treatments if possible in the face of recurrent infections.

DOGS THAT ITCH: DETERMINING THE CAUSE AND STOPPING THE FRENZY!

Valerie A. Fadok, DVM, PhD, Diplomate ACVD
Gulf Coast Veterinary Dermatology and Allergy
Gulf Coast Veterinary Specialists
Houston, TX

Pruritus is one of the most common and frustrating aspects of canine dermatologic disease. Each of us is very familiar with the physical damage that constant scratching causes, but many dogs with chronic itch can also have personality changes that exacerbate the problem. And if they don't have personality changes, their owners surely do! Controlling itch is critical to successful management of canine dermatologic disease. The case of each client and pet should be approached individually, as there is great variation in how much itch each client and pet can tolerate. It is useful to determine the level of itch for each patient, as that determination will allow us to develop a short list of potential causes, which then enables us to develop a rational diagnostic and treatment plan. Most dogs with pruritic skin disease will have diseases that are manageable, not curable. And for most dogs, we can decrease itch but not ablate it. Acknowledging these facts ourselves and helping our clients accept these facts will allow us to have an impact on canine pruritus, one patient at a time.

Triaging dermatology patients requires a good grasp of the history for each dog. Taking a standardized history is very important. Because some owners are better oral historians than others, a dermatology history questionnaire is immensely helpful. If you have a clinic website, you can have these forms available on line and ask your clients to download and fill them out before they come; alternatively, the clients can fill them out while they wait to be seen. You can make this task easy by asking your client to circle or check appropriate responses. This format pleases the minimalist. I do recommend having spaces to write in extra stuff for those detail-oriented clients who like to be complete. These questions can easily fit on one side of a page, allowing you to scan it before your examination:

1. Does your dog itch/scratch/chew/lick/rub?
   Yes No
2. What parts of the body?
   Face Ears Neck Armpits Legs Feet
   Chest Back Belly Stomach/Groin Other
3. On a scale from 1 to 10, how itchy is your dog?
   1 2 3 4 5 6 7 8 9 10
4. Is your dog's itch seasonal or nonseasonal?
   Nonseasonal Seasonal
5. If you circled nonseasonal, are there times of the year when he/she is worse?
   Yes No
6. If you circled seasonal, in what season(s) does your dog itch?
   Spring Summer Fall Winter
7. At what age did your dog start itching?
8. What other pets do you have? Are they itchy?
9. What medications have you used? Which ones worked?
   List Medications Effective Not effective

The next step is a good dermatologic exam. This requires good light and magnification when necessary. I often use the little magnifier on the otoscope to look at lesions. Rolling the dog over and looking at the bottoms of the feet, as well as under the tail is important, as is riffling the coat to see the skin over the back. You will be looking for primary lesions, such as papules, pustules, macules, or nodules. You will also be looking for secondary lesions, such as excoriations, crusts, scale, and alopecia. Gentle otoscopy should also be performed to determine if the dog has an ear infection or whether the ear canals are merely red. During the exam, you can ask the owner which came first, the itch or the lesions. This information is useful as atopic dermatitis has often been termed "an itch that rashes" whereas a disease like scabies has primary lesions of papules which itch.

The next step will be to develop a list of differential diagnoses and a plan by which to sort them out. I usually tell the clients we will develop a short-term plan and a long-term plan to control the itch. The short-term diagnostic plan consists of skin scrapings and cytologies, and maybe a dermatophyte culture if the history and physical exam warrant it. If you live in a flea-ridden area, then using a flea comb as part of your examination is also a good addition to your dermatologic toolbox. Skin scrapings will help us determine if *Demodex* mites are present. If done properly, negative skin scrapings will rule out demodicosis in most cases. Negative skin scrapings NEVER rule out scabies or cheyletiellosis. Skin cytologies help characterize the microbial infections that are present: bacteria, yeast, or both. The short-term treatment plan will be to rule out scabies or cheyletiellosis if indicated, to control fleas if indicated, and to get rid of all microbial infections. Short-term steroid therapy is indicated if the dog is severely pruritic.

In one month, we meet with the patient and client again to determine how much itch has been resolved by treating ectoparasites and microbial infections. Then we develop the long-term plan to control residual itch. The long-term diagnostic plan might be to perform elimination diet testing to rule out food allergy or perform intradermal skin testing or serum allergy testing to discover those antigens contributing to atopic dermatitis/atopy. It will include the judicious use of corticosteroids, antihistamines, and possibly cyclosporine. Diagnostic tests such as bacterial culture and sensitivity or biopsy could be part of either the short term or long-term plan, depending on what the dog looks like during the first exam. Keep in mind that biopsy will not help you sort out the different types of allergic skin disease.

Table I contains a list of common skin diseases and quantification of the itch. Using this table, we will work through a series of patients with pruritic skin disease, discussing the key historical and clinical features, as well as the diagnostic plans, and the treatment plans for each. As a general plan, the following advice is helpful.

Table 1. A Partial List of Pruritic Skin Diseases of the Dog

Intensely Itchy 8–10/10	Moderately Itchy 4–7/10	Mildly Itchy 1–3/10	Variably Itchy 1–10/10
Sarcoptic Mange*	Early uncomplicated atopy	Dry skin	Cheyletiellosis
Food Allergy (some)*	Food allergy (most)	Pyoderma (some)	Demodicosis
Flea Allergy (most)*	Flea allergy (some)	Atopy (few)	Pemphigus foliaceus
Atopy (chronic and/or infected	Pyoderma (many)		Dermatophytosis
Malassezia dermatitis	Contact allergy		Mycosis fungoides
Pyoderma ("staphylococcal hypersensitivity") Staphylococcal colonization			
Acral pruritic nodule/lick granuloma			

* The three most itchy skin diseases

For itch, rule out ectoparasites, rule out infections, rule out food allergy, and then deal with what is left! Usually, what is left is atopy/atopic dermatitis, and these dogs are probably best referred for intradermal skin testing and immunotherapy. Atopic dogs will be high maintenance dogs for the rest of their lives, for both their owners and their veterinarians. The more unusual diseases associated with itch will look unusual; these are patients you will wish to biopsy for a diagnosis or refer for diagnosis and treatment recommendations.

PATIENT 1: MR. BIG, 3-MONTH- OLD MALE POODLE

- **Key historical features**: Young intensely itchy dog purchased at roadside stand
- **Key diagnostic features:** Erythematous papular rash, positive pinnal-pedal reflex, scale and crust on ears, positive cytologies for cocci/yeast, response to treatment (negative skin scrapings a red herring)
- **Treatment**: Topical selamectin every 2 weeks for 3 treatments, oral cefpodoxime and fluconazole, antiseborrheic shampoos (methylprednisolone for pruritus)
- **Final diagnosis:** Sarcoptic mange, with secondary pyoderma and *Malassezia* dermatitis
- **Important points**:
    - o Negative skin scrapings do not rule out sarcoptic mange.
    - o It is important to treat the bacterial and yeast infections associated with mange.
    - o Because *Sarcoptes* induces a hypersensitivity reaction, corticosteroids may be helpful in palliating the itch.

PATIENT 2: KOBY, 9- YEAR-OLD MALE MALAMUTE MIX

- **Key historical features**: Partial response to antibiotics, steroids (mild pruritus a red herring?)
- **Key diagnostic features**: Crusting on ear margins, positive pinnal-pedal reflex, skin scrapings positive for mites, cytology positive for cocci, low thyroid hormone levels
- **Treatment:** Oral ivermectin, oral cephalexin, antiseborrheic shampoos, thyroid supplementation
- **Final diagnosis**: Sarcoptic mange, hypothyroidism, secondary pyoderma
- **Important points**:
    - o Older dogs can get scabies.
    - o Although no other dogs in the house were itchy, they may have been asymptomatic carriers and possible sources of infection for our patient; all in-contact animals should be treated.
    - o Large numbers of mites may be present in debilitated dogs: "Norwegian scabies."
    - o An underlying metabolic disease may predispose to large numbers of mites; the depression associated with hypothyroidism may have made him less itchy with the disease.
    - o Prolonged treatment times may be required for dogs with large numbers of mites.

PATIENT 3: BONNIE, 3-YEAR-OLD FEMALE SPAYED WEST HIGHLAND WHITE TERRIER.

- **Key historical features:** Owners' observations of fleas, short-term response to steroids, insufficient flea control for patient and her housemates
- **Key diagnostic feature:** Presence of fleas on patient, pattern of alopecia, response to treatment
- **Treatment:** Oral Capstar and increased frequency of topical Advantage for patient, oral lufenuron and topical selamectin for cats, treatment of house and yard
- **Final diagnosis**: Flea allergy dermatitis
- **Important points:**
    - o Flea allergy dermatitis requires integrated pest management on all animals in the house.
    - o Sometimes itch control requires only increasing awareness of the flea life cycle and increasing vigor of flea control. Steroids not required for this dog.

PATIENT 4: INGRID, 3-YEAR-OLD FEMALE SPAYED SHEPHERD CROSS

- **Key historical features**: Pruritus at a young age, inappropriate dietary trials, variable response to steroids, no response to treatment for scabies
- **Key diagnostic features**: Failure to respond to treatment for scabies, cytologies positive for cocci and yeast, response to treatment for infections, eventual response to strict dietary trial and food challenges
- **Final diagnosis**: Food allergy, with secondary pyoderma and *Malassezia* dermatitis
- **Important points**:
  - Dietary trials must be complete. All edible treats and toys must be stopped.
  - Infection control can improve the comfort level of food allergic dogs.
  - Food challenges can enable the dog to go back on a commercial diet.
  - Not all food-allergic dogs are refractory to steroids.
  - It may be important to try more than one diet if food allergy is suspected highly.

PATIENT 5: SCHOTZE, 4-YEAR-OLD FEMALE SPAYED SHIH TZU

- **Key historical features**: Nonseasonal pruritus with seasonal flares, exacerbation following move to warmer climate
- **Key diagnostic features**: Skin cytology, response to flea control, response to dietary trial, intradermal skin testing
- **Final diagnosis:** Flea allergy dermatitis, food allergy, atopic dermatitis with secondary pyoderma and *Malassezia* dermatitis
- **Important points**:
  - Dogs can have multiple allergies.
  - Observing response to flea control and food trials requires that the infections be managed.
  - Controlling fleas and elimination diet testing revealed that atopic dermatitis was still a possibility, so skin testing and immunotherapy were pursued.

PATIENT 6: TESSIE BELLE, 1-YEAR-OLD FEMALE SPAYED WEST HIGHLAND WHITE TERRIER

- **Key historical features**: Moderate to severe pruritus with no response to treatment for scabies, breed and source of dog (relinquished to breed rescue society)
- **Key diagnostic features**: No response to treatment for scabies, skin cytologies positive for cocci and yeast, response to infection control, positive blood allergy test, positive intradermal skin test
- **Final diagnosis:** Flea allergy dermatitis and atopy with secondary pyoderma and *Malassezia* dermatitis
- **Important points:**
  - *Malassezia* is an intensely pruritic disorder.
  - *Malassezia* can be brought under control with topical therapy but requires daily bathing for several weeks.
  - Infection control can reduce itch dramatically in atopic dogs.

PATIENT 7: BOUDREAUX, 5-YEAR-OLD MALE CASTRATED LABRADOR CROSS

- **Key historical features:** Poor response to antibiotics, poor response to Depo Medrol, nonseasonal pruritus with waxing and waning nature
- **Key diagnostic features**: Distribution of primary lesions on face, ears, footpads, results of biopsy
- **Final diagnosis**: Pemphigus foliaceus with secondary bacterial pyoderma
- **Important points**:
  - Historical ringer was the seasonal nature of the disease; this dog's pemphigus flares every summer.
  - Primary lesions of pustules and crusted papules on face and ears very suggestive.
  - If skin disease looks strange, biopsy it!

PATIENT 8: CLANCY, 6-YEAR-OLD OLD MALE CASTRATED ENGLISH BULLDOG

- **Key historical features:** Atopic dog on immunotherapy well regulated for 3 years; relapsing prurritus and erythematous plaques, collarettes over last 6 months; poor response to antibiotics and steroids
- **Key diagnostic features:** Negative cytology, skin biopsy, distribution and character of lesions (if it is weird, biopsy it)
- **Final diagnosis**: Epitheliotropic T-cell lymphoma (mycosis fungoides)
- **Important points**:
  - Relapsing itch after years of good control on immunotherapy.
  - Poor response to antibiotics and steroids.
  - Unusual distribution, appearance, and feel of lesions.

DIFFERENTIATING CANINE ALLERGIC SKIN DISEASES

Peter J. Ihrke, VMD, Diplomate ACVD
School of Veterinary Medicine
University of California, Davis, CA

Pruritus is the predominant clinical sign of allergic skin disease. Pruritus is defined as a sensation that elicits the desire to scratch. Together with self-trauma, pruritus is the most common reason for a dog to be presented to a veterinary hospital. Pruritus may be manifested in the dog by licking, chewing, rubbing, hair removal, harassing of owners, irritability, and personality change (lack of tolerance, aggressive behavior). The concept of a *threshold phenomenon* is important in the understanding of pruritus. An individual may tolerate a certain pruritic load without provoking clinical signs but a small increase in that load may push that individual over the threshold initiating clinical signs of pruritus. While some mediators initiate the sensation of pruritus, others simply lower the threshold of pruritus. *"Summation of effect"* occurs whereby additive pruritic stimuli from different coexistent skin diseases may raise an animal above its individual pruritic threshold.

CANINE ALLERGIC SKIN DISEASES – FREQUENCY

Globally, the most common allergic canine skin diseases are, in frequency of occurrence, flea allergy dermatitis, atopic dermatitis, and food allergy (adverse reactions to food). Flea allergy dermatitis is not only the most common skin disease seen in small animal practice in most countries in the world; it is the most common disease of any organ system seen in small animal practice worldwide. Fleas parasitize animals in virtually every area on earth with the exception of locations above 1500 meters elevation and regions such as deserts with very low humidity. However, somewhat surprisingly, flea allergy dermatitis is commonly underdiagnosed all over the world. There are many reasons for this including sociocultural biases against having ectoparasites. The reported frequency of occurrence of different allergic skin diseases varies widely from study to study and is highly controversial. Many dermatologists have expressed the opinion that in parts of the world where fleas are common, flea allergy dermatitis comprises between 50% and 80% of allergic skin disease.

Recent data published by Jackson from a referral dermatology clinic at North Carolina State University offers data on the frequency of atopic dermatitis and food allergy in comparison to each other. However, their data on the frequency of flea allergy dermatitis, and flea allergy seen in conjunction with other allergic skin diseases seems surprisingly low. At UC Davis, our dermatology service sees flea allergy dermatitis as the most common allergic skin disease despite being a referral center.

Jackson and others looked at 91 dogs with allergic skin disease. Here are their results:

- 46% – Atopic dermatitis only
- 23% – Food allergy only
- 20% – Atopic dermatitis & food allergy
- 4% – Food allergy & flea allergy dermatitis
- 3% – Atopic dermatitis, food allergy, & flea allergy dermatitis
- 2% – Flea allergy dermatitis only (bias of a referral center?!)

One can thus extrapolate from these data that 66% have atopic dermatitis, 43% have food allergy, and 20%.of these dogs have both diseases.

DIFFERENTIATING ALLERGIC SKIN DISEASES BY SIGNALMENT PREDILECTIONS

Predilections vary between the three most common allergic skin diseases. Prioritize your index of suspicion based on differences in signalment, history, and physical findings (most common affected sites, lesions).

Breed Predilections

Flea allergy dermatitis can be seen in any breed, but it is more common in "allergic breeds." Atopic dermatitis is most common in the Golden Retriever, Labrador Retriever, Wirehaired Fox Terrier, Dalmatian, West Highland White Terrier, Weimaraner, other small Terriers, Irish Setters, Chinese Shar Pei, and in Spaniels. Food allergy (controversial) may be more common in Labrador Retrievers, Cocker Spaniels, Golden Retrievers, Soft-Coated Wheaten Terriers, Dalmatians, West Highland White Terriers, Collie Dogs, Chinese Shar-Peis, Lhasa Apsos, Springer Spaniels, Miniature Schnauzers, Dachshunds, Boxer Dogs, and German Shepherd Dogs.

Age Predilections

The age of onset varies between different allergic skin diseases. Flea allergy dermatitis can be seen in any age, but is more common in dogs over 6 months of age. The average age of onset of atopic dermatitis is between 1½ and 3 years of age, but it can occur in dogs as young as 6 months (rarely – younger!) and occurs rarely in dogs over 6 years of age. Food allergy is highly variable in onset and can begin from 4 months to 14 years; up to 50% may develop the disease at less than 1 year of age. Useful or reliable sex predilections have not been reported.

History Predilections

As far as speed of onset, flea allergy dermatitis usually is of rapid onset. In contrast, atopic dermatitis usually is insidious and gradual in onset. Food allergy usually is insidious and gradual in onset, but occasionally may be more rapid in onset.

Seasonality Predilections

Flea allergy dermatitis is contingent on flea availability, which depends on weather, seasonal temperature and humidity changes, and severity of winters. Atopic dermatitis is contingent on allergen availability, and commonly may begin seasonally (summer), but annually adds time spring & fall, and finally becomes year around. Food allergy should not be seasonal.

Physical Findings – Site Predilections

Flea allergy dermatitis affects predominantly the caudal half of the dog, and is bilaterally symmetric involving the dorsal lumbosacral, tailbase, perineum, medial and caudal thighs, and umbilical regions. Atopic dermatitis most commonly affects the face, paws, distal extremities, ears, ventrum, and caudal carpus. Food allergy affects the face, ears, extremities, paws, and ventrum (similar to atopic dermatitis).

Physical Findings – Lesions

Lesions of flea allergy dermatitis include crusted papules, erythema, and excoriations. Chronic changes are lichenification, hyperpigmentation, alopecia, fibropruritic nodules, and secondary infection. Atopic dermatitis initiates self-trauma leading to erythema, alopecia, excoriation, and the chronic changes of lichenification and hyperpigmentation, and secondary infections. Few "primary" lesions are seen. Food allergy initiates self-trauma leading to erythema, alopecia, and excoriation. Chronic changes include lichenification and hyperpigmentation, and secondary infections. Few "primary" lesions are seen, similar to atopic dermatitis.

DIFFERENTIATING ALLERGIC SKIN DISEASE BY RULING OUT FLEA ALLERGY AND FOOD ALLERGY

There are no laboratory tests available that consistently can rule in or out allergic skin disease in the dog. Therefore, since flea allergy dermatitis is the most common allergic skin disease, it is logical to rule out flea allergy by several months of strict flea control. If pruritus remains after strict flea control, initiate a strict elimination diet to rule out food allergy.

Ruling Out Flea Allergy Dermatitis

One must convince the owner that flea allergy may be the correct diagnosis. In order to accomplish this, one must defuse cultural bias, explain why fleas are not seen, and explain that flea allergy is the most common disease on the planet. Then, show defects in current or past flea control. These defects include not treating all animals, not treating in-and-out cats, lack of consistency, and substitution of over-the-counter products, and extreme environmental issues. Institute modern flea control for 6 to 8 weeks ("Prove me wrong!").

Ruling Out Food Allergy

Convince the owner that an elimination diet must be incredibly strict. Then show defects in past attempted elimination diets (snacks, food with medicine, flavored heartworm preventatives, IDIs, or other medications, and flavored toothpaste). Institute a strict elimination diet for 8–12 weeks. If there is improvement, continue the diet. Do not accept food allergy as the diagnosis without rechallenge with the original diet! When rechallenging with the initial food, do not change anything else in the treatment regimen (antibiotics, anti-yeast medications, flea control, antihistamines, and topical therapy).

Ruling in Atopic Dermatitis

Canine atopic dermatitis is a diagnosis of exclusion. "Allergy testing" (either intradermal testing or allergen-specific IgE serology) are performed *only* in animals that meet the clinical criteria of atopic dermatitis and where other pruritic skin disease that can be more readily diagnosed definitively have been ruled out. Testing is *only* performed to select antigens in animals where the decision already has been made to embark on the lifetime pathway of allergen specific immunotherapy.

MANAGEMENT OF CONCURRENT SKIN DISEASES

Allergic skin diseases commonly coexist. One must manage **all** allergic skin diseases present to be successful, thus reducing the animal below pruritic threshold. Concurrent confirmed or suspected flea allergy dermatitis must be managed. Concurrent secondary pyoderma or bacterial overgrowth and *Malassezia* dermatitis also must be managed.

CANINE AND FELINE DEMODICOSIS: WHERE ARE WE NOW?

Peter J. Ihrke, VMD, Diplomate ACVD
School of Veterinary Medicine
University of California, Davis, CA

CANINE DEMODICOSIS

Canine demodicosis is a common noncontagious parasitic skin disease caused by an overpopulation of the host-specific follicular mites of the genus *Demodex*. Most cases of canine demodicosis are caused by *Demodex canis*, although two other species of demodicid mites are reported. Localized demodicosis is a common mild and benign self-limiting disease. In contrast, generalized demodicosis is a serious and potentially life-threatening disease. Most cases of generalized demodicosis are juvenile in onset and develop in dogs less than 1 year of age.

A genetically preprogrammed immunologic defect probably is responsible for the juvenile-onset, generalized demodicosis. Immunosuppressive diseases (hyperglucocorticoidism, iatrogenic hyperglucocorticoidism, lymphoid neoplasia, leishmaniasis, and hypothyroidism) can induce adult-onset demodicosis. Marked breed predilections and clustering in litters support a hereditary basis for juvenile-onset generalized demodicosis. Data suggests an autosomal recessive mode of inheritance. The American Academy of Veterinary Dermatology (AAVD) adopted a resolution in 1981 sponsored by Dr. Robert Kirk recommending "neutering all dogs who have had generalized demodicosis so that the incidence of the disease is decreased and not perpetuated."

Generalized canine demodicosis is characterized by the progression of multifocal, erythematous, partially alopecic, crusted macules that eventuate in plaques. Boggy, crusted plaques, alopecia, and exfoliation are signs of more severe disease. Hyperpigmentation, lichenification, and scarring develop with chronic infection. Secondary bacterial infection with generalized deep folliculitis and furunculosis, occasional cellulitis, and tissue devitalization may contribute greatly to disease severity, morbidity, and mortality. Hair loss may be surprisingly minimal in long-coated breeds with long anagen hair cycles such as the Maltese, Shih Tzu, Lhasa Apso, and Miniature Poodle; this may lead to a decreased suspicion for demodicosis.

Diagnosis

Diagnosis is not difficult in most dogs with demodicosis. Skin scrapings or hair plucking readily demonstrate mites. A medium grade of mineral oil is used for skin scrapings. Micro-spatulas (Fisher Scientific catalog #21-401-20) are excellent tools for performing skin scrapings. Hair plucks are a less sensitive, but gentler method of obtaining mites. The author uses hair plucks predominantly in areas such as the periorbital region where performing a skin scraping may be difficult. Recently, impression smears of exudative lesions have been shown to be an additionally useful method of diagnosing demodicosis. Skin biopsy may be required to rule out demodicosis if the disease is chronic, severely affects the feet, or in the Chinese Shar Pei.

Treatment

Treatment of **canine generalized demodicosis** remains challenging. There is no treatment for generalized demodicosis that is 100% effective, even though multiple options currently are available. However, most dogs can be successfully managed long-term. Corticosteroid usage must be avoided.

Secondary deep pyoderma usually coexists with canine generalized demodicosis and must be treated aggressively. Antibiotics such as cephalexin, enrofloxacin, marbofloxacin, and clavulanic acid-potentiated amoxicillin are used most commonly and usually are continued for a minimum of 8 weeks.

Topical adjunctive therapy is beneficial. Antibacterial and follicular flushing shampoos containing benzoyl peroxide aid greatly in management of both demodicosis and secondary pyoderma. Whirlpool baths using chlorhexidine remove debris and encourage drainage in severely affected dogs.

Amitraz (Mitaban®, Pfizer Animal Health) remains the only FDA-approved treatment for generalized canine demodicosis. Before amitraz rinses, all medium- and long-coated dogs should be clipped and the hair kept short throughout therapy. Clipping plus benzoyl peroxide–containing shampoos afford better penetration of the dipping solution. Mitaban is diluted according to label directions in the US (0.025% solution) and applied every 2 weeks. A stronger amitraz solution (0.050% solution) has been used on a weekly basis routinely in Germany, Australia, and elsewhere. Using evidence-based medicine, good evidence is available for the efficacy of amitraz rinses (0.025%–0.05% solutions) used every 1 or 2 weeks.

Amitraz rinsing should be performed either outdoors or in an open garage. Rubber gloves should be worn by the applier. Amitraz is an MAO inhibitor and should not be used by anyone taking other MAO-inhibiting drugs. Continuous rinsing of the entire dog with the dipping solution and soaking of the feet in the solution should continue for 15 minutes. The dog should be kept as dry as possible (avoiding of walking on wet lawns) between rinses.

Amitraz rinses should be continued every 2 weeks until multiple negative skin scrapings and hair plucks (no adults, larvae, or eggs) are achieved. After negative scrapings and hair plucks have been achieved, three additional rinses should be performed. After three additional rinses, reexamination should include 6 to 10 skin scrapings and hair plucks before rinses are terminated. It is not uncommon for 10 to 15 rinses to be required before negative scrapings are achieved.

Side effects of amitraz therapy include lethargy, weakness, ataxia, hyperglycemia, polyuria, hypothermia, and bradycardia. Atipamezole (Antisedan®, Pfizer Animal Health)(50 μg/kg, IM) and yohimbine (0.11 mg/kg, IV; 0.25 mg/kg, IM) may be used as a pretreatment in dogs with previous reactions to amitraz or can be used as antidotes for toxicity.

Resistant cases may require off label application of amitraz rinses weekly rather than biweekly. In cases that are controlled but not cured, a maintenance program of rinses every 1 to 2 weeks may be instituted to keep mite numbers low and clinical signs minimized. Dogs with adult-onset demodicosis and concurrent immunosuppressive diseases frequently require extended therapy regimens.

Ivermectin (Ivomec®, Merial) is a commonly used, but unapproved, treatment for generalized canine demodicosis. Many of the dogs referred to the University of California have failed amitraz therapy. These dogs are treated with ivermectin given daily per os at a dosage between 400 and 600 µg/kg daily. High-dose ivermectin is the most efficacious and cost-effective treatment for generalized demodicosis that is nonresponsive to amitraz. Using evidence-based medicine, good evidence is available for the efficacy of ivermectin given per os (300–600 µg/kg daily).

Severe adverse reactions to ivermectin have been reported in both dogs and cats. Collies are particularly sensitive with over 75% of Collies being either carriers or homozygous for the dangerous mutant MDR1 allele leading to neurotoxicity. Information on testing for this mutation can be found at http://www.vetmed.wsu.edu/depts-vcpl/ Other herding breeds such as the Shetland Sheepdog, Australian Shepherd, and Border Collie also may be at increased risk for toxicity. However, idiosyncratic toxicity may be seen in any breed.

Similar to the monitoring of efficacy used with amitraz topical therapy, dogs are reevaluated monthly until multiple negative skin scrapings and hair plucks (no adults, larvae, or eggs) are achieved. After negative scrapings and hair plucks have been achieved, therapy is continued for an additional 2 months. Two months beyond the last negative skin scraping and hair pluck, reexamination should include 6 to 10 skin scrapings and hair plucks before therapy is terminated. It is not uncommon for 4 to 6 months of therapy to be required before negative scrapings are achieved.

Milbemycin oxime (Interceptor®, Novartis) is another commonly used, but unapproved, treatment for generalized canine demodicosis. It is used less frequently than ivermectin as milbemycin therapy is considerably more expensive. However, milbemycin is the safest avermectin used for the treatment of demodicosis. In dogs that have failed amitraz therapy, milbemycin oxime is the treatment of choice for generalized demodicosis in herding breeds such as the Collie. Milbemycin also is recommended for small dogs based on cost. Milbemycin is given daily per os at a dosage of 2 mg/kg daily. Using evidence-based medicine, good evidence is available for the efficacy of milbemycin given per os (2 mg/kg daily).

Milbemycin therapy is considerably less toxic than ivermectin therapy. Side effects are rare, but at high dosages may include vomiting, stupor, trembling, and ataxia.

Identical to the monitoring of efficacy used with ivermectin oral therapy, dogs are reevaluated monthly until multiple negative skin scrapings and hair plucks (no adults, larvae, or eggs) are achieved. After negative scrapings and hair plucks have been achieved, therapy is continued for an additional 2 months. Two months beyond the last negative skin scraping and hair pluck, reexamination should include 6 to 10 skin scrapings and hair plucks before therapy is terminated. It is not uncommon for 4 to 6 months of therapy to be required before negative scrapings are achieved.

Moxidectin (ProHeart® 6, Fort Dodge Animal Health), currently not available in the US, also has been used as another unapproved, treatment for generalized canine demodicosis. Evidence-based medicine indicates good evidence for the efficacy of moxidectin given per os (400 µg/kg daily).

FELINE DEMODICOSIS

Feline demodicosis is a rare or regional skin disease caused by at least three different species of demodectic mites. Feline superficial demodicosis is a contagious, transmissible frequently pruritic generalized skin disease caused by the surface-dwelling *Demodex gatoi*. Feline follicular demodicosis caused by the feline follicular mite, *Demodex cati* resembles *Demodex canis* infection in dogs.

Feline superficial demodicosis does not have a canine counterpart. It is believed to be rare in most of North America, but is found more commonly in localized enzootic regions of the southern and southeastern US. Feline superficial demodicosis may be increasing in frequency where modern insect-specific parasiticides that do not kill acarids are used for flea control. Clinical features vary from asymptomatic alopecia to alopecia with variable pruritus and self-trauma. If pruritus is absent, cats can present with diffuse, bilaterally symmetric alopecia, plus or minus scaling, affecting the ventral and lateral trunk and caudal legs. Pruritus, if present, usually is intense leading to erythema, crusting, and excoriation. Skin scrapings may not yield mites or eggs in pruritic cats since excessive grooming can remove surface-living mites. Skin scrapings of non-pruritic cats may yield large numbers of mites.

Feline follicular demodicosis due to *D. cati* is rare and may present as either localized or generalized follicular demodicosis. Similar to canine localized demodicosis, feline localized demodicosis is a mild and self-limiting disease. Similar to canine generalized demodicosis, feline generalized follicular demodicosis due to *D. cati* and seems to require diminished immune response. Immunosuppressive diseases such as feline immunodeficiency virus infection (FIV), feline leukemia virus (FeLV), diabetes mellitus, hyperglucocorticoidism, and neoplasia may initiate feline generalized follicular demodicosis.

Feline generalized follicular demodicosis is a less severe disease than canine generalized demodicosis. Predominantly asymptomatic and subtle erythema with variable alopecia, scaling, and crusting may be seen. Lesions most commonly affect the face, neck, trunk, or extremities. Systemic signs referable to underlying immunosuppressive systemic diseases may be noted.

Treatment

For the treatment of feline demodicosis, there is good evidence-based information to recommend lime sulfur rinses (LymDyp®, DVM Pharmaceuticals) (2%) weekly. There is fair evidence to support the use of amitraz rinses (0.0125%) weekly. (See additional information above under the treatment of canine generalized demodicosis.)

NEWLY DESCRIBED BREED-BASED SKIN DISEASES

Peter J. Ihrke, VMD, Diplomate ACVD
School of Veterinary Medicine
University of California, Davis, CA

Signalment (age, breed, sex) predilections are becoming much more important in all branches of clinical medicine as more epidemiologic data are accrued. Breed predilections are seen as a feature of many skin diseases of the dog and cat. These breed predilections can aid diagnosis via prioritizing differential diagnosis based on likelihood of occurrence in that breed. Some diseases have such striking breed predilections that it may greatly facilitate diagnosis. Diseases with strong breed predilections are likely to have an inherited basis.

Since the year 2000, multiple new breed-based skin diseases have been reported in dogs and cats. Three "new" skin diseases affecting the planum nasale and philtrum of dogs and cats have been diagnosed. All three diseases have marked breed predilections. Another disease seen in Persian and Himalayan cats has been noted occasionally by dermatologists for many years but was not described until 2000. The first report of proliferative necrotizing otitis of kittens was published in 2005 in a textbook.

NASAL PARAKERATOSIS OF LABRADOR RETRIEVERS

Nasal parakeratosis of Labrador retrievers is a rare syndrome characterized by proliferative changes of the planum nasale. Autosomal recessive inheritance is hypothesized. Clinical features included dry, rough, proliferative keratinous adherent debris forms on the planum nasale. Lesions are most severe dorsally. The planum may change color from black to gray or brown. Owners have noted that the affected planum becomes paler after the surface is wet. Deep fissuring can initiate secondary infection. Affected dogs are otherwise healthy. In early stages, the process does not ablate the normal cobblestone appearance. Later, the process may ablate the normal architecture. This syndrome is seen exclusively in Labrador retrievers or their related crossbreeds. Black, yellow, and chocolate Labrador retrievers have been reported. Lesions develop between 6 months and 1 year of age and 13 of 18 affected dogs were males. The disease is visually distinctive. Possible differential diagnoses include nasodigital hyperkeratosis, zinc-responsive skin dermatosis, discoid lupus erythematosus, and pemphigus foliaceus.

There is no cure for this genodermatosis. Topical petroleum jelly or topical propylene glycol in water have been used with palliative success. Topical therapy must be continued long-term.

PROLIFERATIVE ARTERITIS OF THE NASAL PHILTRUM (SAINT BERNARDS)

Proliferative arteritis of the nasal philtrum is a rare and distinctive vascular disease affecting the nasal philtrum. The etiology is not known. An inherited disorder is strongly suspected as 4 of 5 dogs reported were Saint Bernards and 3 of 4 were closely related. The disease is characterized clinically by solitary, well-demarcated linear ulcers with adherent hemopurulent crusts affecting the nasal philtrum. Ulcers ranged in size from 3 to 5 cm in length, 2 to 15 mm in width, and 2 to 5 mm in depth. Arterial hemorrhage of variable severity occurred in all dogs. Affected dogs are otherwise healthy.

Progression is unclear. Affected dogs have experienced long-term problems with periodic more severe ulcerations. Four of 5 dogs were Saint Bernards and the fifth dog reported was a Giant Schnauzer. The syndrome is tardive in onset and affects adult dogs between 3 and 6 years of age. The disease is visually distinctive. Immediate surgical intervention is required if severe arterial bleeding is noted. Oral anti-inflammatory dosages of corticosteroids, topical corticosteroids, tetracycline and niacinamide, and omega-3 (fish oil) fatty acids have been palliative in some dogs. Treatment must be continued long-term.

ULCERATIVE PLANUM NASALE OF THE BENGAL CAT

Ulcerative planum nasale of the Bengal cat is a rare and distinctive skin disease characterized by fissures, crusts, and ulcers of the planum nasale reported only in Bengal cats. A defect resulting in high epidermal turnover and reduced thickness of the stratum corneum was hypothesized. An inherited disorder is strongly suspected as all affected cats have been Bengal cats. The disease has been seen in Sweden, Italy, the United Kingdom, and in the US (two cases in Northern California). Clinical features include scaling progressing to adherent crusting overlying erosions and ulcers. Pruritus or pain were not noted. Bleeding can occur. The disease is gradual in onset in Bengal cat kittens or young adults. Age of onset was between 4 months and 1 year of age. The disease is visually distinctive. Oral prednisolone and topical salicylic acid were palliative in some cats. Topical tacrolimus (Protopic^{R}) was very effective in a small number of cats. Lesions in some cats may resolve spontaneously.

FACIAL DERMATITIS OF PERSIAN AND HIMALAYAN CATS

Facial dermatitis is an uncommon and progressive, idiopathic facial inflammatory skin disease reported in young Persian and Himalayan cats. It is presumed to be inherited.

Tightly adherent, darkly colored, greasy or waxy debris mats the facial hair. Erythema and exudation occur as the syndrome becomes chronic. Lesions usually are more severe in the facial folds, but also are present in non-intertriginous locations. A bilaterally symmetric ceruminous otitis externa was seen in about half of the Persian cats seen by Bond. The muzzle, periorbital regions, and chin are affected. Less severe lesions may affect body regions beyond the head. Secondary pyoderma or secondary *Malassezia* dermatitis may increase severity of clinical signs.

Pruritus commonly becomes intense with chronicity. Submandibular lymphadenopathy may be noted.

Affected Persian cats first present between 10 months and 6 years of age. Males may be slightly over-represented. In addition to published reports, multiple other Persian and Himalayan cats have been seen by various dermatologists worldwide.

Facial dermatitis of Persian and Himalayan cats is visually distinctive. Clinical differential diagnoses are few. Adherent dark facial debris may be seen with severe feline acne. A primary seborrhea of Persian cats has been reported, but other body regions beyond the face frequently are affected.

PROLIFERATIVE NECROTIZING OTITIS OF KITTENS

(I am cheating a bit with this last disease; most cases have been seen in domestic shorthaired cats.) Proliferative necrotizing otitis of kittens is a rare, highly characteristic syndrome of unknown etiology. The syndrome is seen only in cats less than one year of age. An immunologic basis is suspected since the syndrome bears some resemblance histopathologically to hyperkeratotic erythema multiforme. At this time, there is no evidence to link this syndrome to infectious viral diseases. Polymerase chain reaction (PCR) testing for feline herpesvirus 1 has been negative in a small number of cats. Papillomavirus immunohistochemistry also has been negative.

Erythematous, well-demarcated plaques with adherent, thick keratinous debris develop on the medial aspect of the pinnae, the entrance to the auditory canal, and in some cats, the preauricular region of the face. Lesions develop rapidly and coalesce creating annular or serpiginous borders. Adherent crusts cover the lesions and become trapped in the hair coat. Erosion and ulceration occur as the syndrome progresses. The syndrome usually is asymptomatic. Mild pruritus or discomfort is noted when ulceration is present.

Lesions develop in kittens between 2 months and 6 months of age and regress spontaneously between 1 and 2 years of age. Most cases have occurred in Domestic Shorthaired Cats. Proliferative necrotizing otitis of kittens is visually distinctive. Diagnosis is confirmed by skin biopsy.

ECTOPARASITICIDAL THERAPY

Peter J. Ihrke, VMD, Diplomate ACVD
School of Veterinary Medicine
University of California, Davis, CA

FLEAS AND FLEA ALLERGY DERMATITIS

Flea allergy dermatitis is the most common skin disease seen in small animal practice in most countries in the world. Fleas parasitize animals in virtually every area on earth with the exception of locations above 1500 meters elevation and regions such as deserts with very low humidity. The cat flea, *Ctenocephalides felis,* is the primary flea species associated with flea infestation and flea allergy dermatitis in both dogs and cats. The average cat flea life cycle involving development through egg, larvae, pupa, and cocoon, and the adult takes between 3 and 4 weeks. However, the life cycle can be as short as 12 days or as long as 140 days. Adult cat fleas are obligate permanent ectoparasites, attracted to the host by warmth, movement, changes in light intensity, and respiratory carbon dioxide.

Advances in understanding flea biology and new methodologies available to combat multiple life stages of the flea have revolutionized our ability to deal with this disease. It is crucial to remember that the adult cat flea is an obligate parasite. However, since the bulk of the flea lifecycle (eggs, larvae, and pupa) occurs in the environment, environmental issues must always be addressed. Historically, flea control has required vigorously treating both the animal and the environment with a combination of insecticides and, more recently, insect growth regulators. Today, either topical or systemic anti-flea therapy may be the only management required. The new agents that have created this paradigm shift include imidacloprid, fipronil, selamectin, nitenpyram, lufenuron, methoprene, and pyriproxifen.

Skin disease associated with fleas is a complex hypersensitivity involving at least four immunologic processes: immediate hypersensitivity, late-onset immediate hypersensitivity, delayed hypersensitivity, and cutaneous basophil hypersensitivity. Blood consumption by female fleas averages 13.6 µL/day (75 female cat fleas can consume 1 mL/day). The majority of blood is passed out as partially digested feces to feed flea larvae.

The management of flea allergy dermatitis requires the prevention of flea bites plus the disruption of the life cycle of the flea. New products that have become available over the past 15 years have exponentially increased our ability to initiate flea control and manage flea allergy dermatitis.

Modern Flea Control

New, considerably less toxic prescription products that also are much easier to use are available that kill adult fleas and disrupt the flea life-cycle. Most insecticides can effectively kill fleas; preventing reinfestation is the problem. Ensuring long-term pet owner compliance is required for ongoing flea control. The comparatively recent development of both insecticides and insect growth regulators with novel and convenient dosage forms (such as spot-ons, collars, and oral products) coupled with prolonged residual activity has dramatically improved pet owner compliance and hence prevented reinfestations. Although insecticidal resistance most often is suspected when flea control measures have failed, lack of control more often results from lack of understanding of flea biology, poor application technique, or too infrequent reapplication of the products.

The goals of flea control should be elimination of existing fleas on affected animals, continued elimination of fleas acquired from infested premises, and the prevention of reinfestation. In order to accomplish these goals, an integrated flea control plan must be instituted. Effective residual adulticides must be used to kill fleas and provide residual killing activity and insect growth regulators should be used to used to disrupt flea reproduction. In addition, mechanical control procedures such as cleaning the pet's blankets, beds, pet carriers, and throw rugs and vacuuming or removing furniture that can house pre-adult fleas must be instituted. Prevention of pests that can carry fleas (rats, opossums, squirrels, raccoons, skunks, feral cats) from entering crawl spaces, foundation vents, porches, and garages also is important.

Modern Flea Control Products

New spot-on prescription products display superior efficacy, safety, and residual activity. These products need to be applied directly to the skin, not to the haircoat. Our strong clinical impression at UC Davis is that dogs and cats with severe flea hypersensitivity experience much better efficacy with these products applied every 3 weeks rather than monthly. Our clinical impression remains that either bathing or swimming degrades the efficacy of all of these products. Over-the-counter (OTC) competing products commonly are advertised as "just as good as what you can get from your veterinarian" plus "less expensive." In general, these products contain concentrated permethrin or other synthetic pyrethroids. All indications are that these OTC products do not have either the efficacy, residual activity, or the safety profile of the spot-on prescription products. Figure 1 summarizes the opinions of the author.

Personal Recommendations

Flea control must be regionalized and often personalized based on severity of possible infestation in your locale, number of dogs and cats in the environment, indoor/outdoor status, infested pests and strays in the environment, finances of the owner, and severity of disease versus magnitude of the infestation. The "average" dog or cat will respond to fipronil and S-methoprene, imidacloprid with or without lufenuron, or selamectin as sole therapy. Severely flea-allergic dogs will require fipronil and S-methoprene or imidacloprid plus permethrin, plus nitenpyram, with or without lufenuron. Severely flea-allergic cats will require spot-on preparations plus nitenpyram with or without lufenuron. Pump-sprays also may be beneficial as an adjunct.

TICKS

Tick infestation and tick bite hypersensitivity are highly variable regional skin diseases. In some parts of North

America, ticks are a major problem, while they are comparatively rare in many other areas. Ticks cause morbidity either by direct irritation from their bites, initiate hypersensitivity, or act as vectors for multiple bacterial, viral, rickettsial, or protozoal diseases. The author's comments on these products are presented in Figure 2.

Personal Recommendations

Tick control must be regionalized and personalized based on severity of possible infestation in your locale, number of dogs, indoor/outdoor/run free status, infested pests and strays in the environment, finances of the owner, and severity of disease vs. magnitude of infestation. 'The average dog' will respond to fipronil and S-methoprene, imidacloprid and permethrin, selamectin, or an amitraz collar as sole therapy. Severely affected dogs benefit from the combination of a spot-on product (fipronil and S-methoprene, imidacloprid and permethrin, or selamectin) plus an amitraz collar.

ACARIASIS – SARCOPTIC ACARIASIS, NOTOEDRIC ACARIASIS, CHEYLETIELLOSIS

Canine sarcoptic acariasis or "scabies" is an intensely pruritic, highly contagious, transmissible canine dermatoses caused by the epidermal mite *Sarcoptes scabei var. canis*. Transmission is usually by direct contact with an infested dog. Evidence supports clinical disease being a multifactorial hypersensitivity reaction. Sarcoptic acariasis may be increasing in prevalence with the advent and increased popularity of newer insect-specific flea control products. Formerly, we may have stopped scabies infestation when we were simply attempting to kill fleas. The author's comments on available products are provided in Figure 3.

Notoedric acariasis or feline scabies is a rare contagious mite infestation caused by the sarcoptid mite *Notoedres cati* characterized by crusting with extreme pruritus. The disease is rare in most parts of the United States, but may be found in localized endemic areas. Similar to sarcoptic acariasis, notoedric acariasis may be increasing in prevalence. *Notoedres* is highly contagious in cats and occasionally, may affect dogs or humans.

Cheyletiellosis is a contagious mite infestation seen in domestic animals, wildlife, and humans characterized primarily by scaling and crusting caused by different, but similar, species of *Cheyletiella* mites. Pruritus is variable. It may be seen more commonly in areas of the world where concerted flea therapy is not necessary or not consistent. *Cheyletiella* dermatitis may be increasing in prevalence on a wider basis with the advent of newer insect-specific flea control products. Infestations have been reported in dogs, cats, rabbits, squirrels, poultry, foxes, and humans. This disease may not be as uncommon as previously thought, since veterinarians may have a low index of suspicion. **Cheyletiella** mites may live in the environment for extended periods of time.

Modern Contagious Acarid Control Products

It is beneficial for the management of all three acarid infestations to isolate the affected animal(s) and clean the premises, and dispose of the animal's bedding or thoroughly cleanse it. For the management of canine sarcoptic acariasis, all dogs on the premises and any other dogs with significant contact with the affected dog should be treated. For the management of feline notoedric acariasis, all cats on the premises and any other cats with significant contact with the affected cat should be treated. The treatment of in-contact cats in households with canine sarcoptic acariasis and the treatment of in-contact dogs in households with feline notoedric acariasis are more controversial. If skin disease is present or if initial species-restricted therapy is ineffectual, treatment of the other species should be considered. All dogs and cats on the premises and any other dogs or cats with significant contact with the affected animal should be treated when cheyletiellosis is diagnosed.

The traditional approach of using weekly keratolytic shampoos followed by parasiticidal dips has been superseded by newer less labor-intensive methods of therapy. Lime sulfur (LymDip®, DVM Pharmaceuticals, Lime Plus Pet Dip®, DermaPet) is still used in circumstances where safety is an issue, especially in very young animals. Systemic corticosteroids may be used adjunctively to control pruritus during the first week of therapy. Paradoxically, pruritus may actually increase during initial therapy perhaps due to increased antigenic load. The comments of the author on these products are presented in Figure 3.

Personal Recommendations

It is important to maintain an index of suspicion for all three acarid infestations as a cause of skin disease in dogs and cats. Cheyletiellosis may present as exfoliation with minimal pruritus. All three contagious mite infestations may be increasing in frequency of occurrence. Most dogs and cats with mite infestations will respond to selamectin, ivermectin, or milbemycin. Based on approval for use on dogs and cats for mite infestations, selamectin is the drug of choice for all three mite infestations. If financial constraints preclude usage, ivermectin or milbemycin can be used as alternatives.

Figure 1. Modern Flea Control Products

Imidacloprid (Advantage®, Bayer; Canada – Imidacloprid & Moxidectin - Advantage Multi®, Bayer; Europe – Advocate®, Bayer)
Advantages – larvicidal on the animal and kills/debilitates adult fleas on contact, ease of application
Disadvantages – does not have repellent action, diminished efficacy after bathing or swimming, does not have activity against ticks, occasional application site reactions
Bottom-line – Good narrow-spectrum product for fleas

Fipronil & S-Methoprene (Frontline® Plus, Merial), Fipronil (Frontline® Spray, Merial)
Advantages – Kills adult fleas, disrupts flea life cycle, ease of application, kills ticks, spray: rapid dispersion/coverage
Disadvantages – Does not have repellent action, some diminished efficacy after bathing or swimming, occasional application site reactions, spray is labor-intensive
Bottom-line – Good broader spectrum product

Imidacloprid & 44% permethrin (Advantix®, Bayer)
Advantages – Larvicidal on the animal and kills/debilitates adult fleas on contact, interrupts flea life cycle, repellant 'flushing' activity of permethrin, ease of application, also kills ticks and mosquitoes
Disadvantages – Dog-only product, do not use on cats, diminished efficacy after bathing or swimming, occasional application site reactions?
Bottom-line – Good broader spectrum product, dog only product

Selamectin (Revolution® [USA]; Stronghold® [Europe], Pfizer)
Advantages – Broad spectrum against many internal and external parasites, kills adult fleas plus larvae and eggs, kills ticks, kills many contagious ectoparasitic mites (*Sarcoptes, Notoedres, Cheyletiella, Otodectes*), ease of application
Disadvantages – Does not have repellent action, diminished efficacy after bathing or swimming, slower efficacy?, application site reactions?
Bottom-line – Good broader spectrum product

Nitenpyram (Capstar™, Novartis)
Advantages – Very rapid response with visual results, kills 100% of adult fleas within 6 hours, short-acting, ease of oral administration, give every 24–72 hours (half-life in dogs is 2.8 hours, half-life in cats is 7.7 hours) very safe product, adverse reactions not seen yet
Disadvantages – Does not have repellent action, does not disrupt flea life cycle, short-acting, does not have activity against ticks
Bottom-line – Good narrow spectrum product, use with spot-ons initially for rapid response, not for use as sole therapy, use in dogs requiring frequent shampooing, compliance problems?

Lufenuron (Program®, Novartis; Sentinel® [lufeneron + milbemycin oxime])
Advantages – Oral product, very safe product without known mammalian toxicity, adverse reactions not seen yet
Disadvantages – Does not kill adult fleas or pupa, time lag – 60–90 days required to disrupt flea life cycle, does not have repellent action, adult flea must feed on animal to ingest, does not have activity against ticks, must give with food
Bottom-line – Use with spot-ons for long-term control, not for use as sole therapy unless very closed environment, treat all animals, use in dogs requiring frequent shampooing, compliance problems?

Imidacloprid & Moxidectin – (Advantage Multi®, Bayer; Europe – Advocate®, Bayer)
Advantages – Broad spectrum against many internal and external parasites, larvicidal on the animal and kills/debilitates adult fleas on contact, ease of application, ear mites, sarcoptic acariasis?
Disadvantages – Does not have repellent action, diminished efficacy after bathing or swimming, does not have activity against ticks, application site reactions.
Bottom-line – Good broader spectrum product

Pyriproxifen (Nylar®) containing collars – (Pyriproxifen & amitraz collars (Preventic PLUS®, Virbac), dogs only!, no longer available in the US, Pyriproxifen & 2% permethrin (KnockOut® Collar for Dogs, Virbac), no longer available in the US, Pyriproxifen (KnockOut® Cat & Kitten Collar for Dogs, Virbac), no longer available in the US)
Advantages – Ovicidal and larvicidal for fleas, UV stable juvenile hormone analogue, translocates to bedding, IGR efficacy for 3 months, Preventic Plus® adds tick protection
Disadvantages – long-term residual status may affect beneficial insects
Bottom-line – very useful adjunct to spot-ons or spray products, useful in dogs requiring frequent shampooing

Figure 1 (Continued).

Synthetic pyrethroid containing pump sprays (variety of manufacturers)
Advantages – Daily use in dogs requiring frequent shampooing
Disadvantages – Frequency of application, compliance, poor residual activity
Bottom-line – Rarely used as sole therapy unless very closed environment, use in dogs requiring frequent shampooing, compliance problems

Metaflumizone spot on preparation (ProMeris™ for cats, Fort Dodge; new product)
Advantages – Kills/debilitates adult fleas on contact, ease of application, stops egg production?
Disadvantages – Does not have repellent action, diminished efficacy after bathing or swimming?, does not have activity against ticks, application site reactions?
Bottom-line – New product awaiting judgment

Metaflumizone & Amitraz spot-on preparation (ProMeris Duo™for dogs, Fort Dodge; not yet available in US)
Advantages – Kills/debilitates adult fleas on contact, ease of application, stops egg production?, efficacy against ticks
Disadvantages – Dog only product, does not have repellent action, diminished efficacy after bathing or swimming?, application site reactions?
Bottom-line – Currently not available in the US

Pyriprole spot on preparation (PracTic, Novartis in Europe; not available in the US)
Advantages – Kills/debilitates adult fleas on contact, ease of application, efficacy against ticks
Disadvantages – Does not have repellent action, diminished efficacy after bathing or swimming?, application site reactions?
Bottom-line – Product not available in the US

Future flea products?
Lilly Companion Animal Health
Summit Vet Pharm

Figure 2. Modern Tick Control Products

Fipronil & S-Methoprene (Frontline® Plus, Merial), Fipronil (Frontline® Spray, Merial)
Advantages – Kills ticks, ease of application, residual activity, and also kills fleas
Disadvantages – Does not have repellent action, some diminished efficacy after bathing or swimming, occasional application site reactions
Bottom-line – Good product for tick control

Imidacloprid & 44% permethrin (Advantix®, Bayer)
Advantages – Kills ticks, ease of application, also kills fleas and mosquitoes
Disadvantages – Dog only product, do not use on cats, diminished efficacy after bathing or swimming, occasional application site reactions?
Bottom-line – Good broad-spectrum product, dog only product!

Selamectin (Revolution® [USA]; Stronghold® [Europe], Pfizer)
Advantages – Kills ticks, also broad spectrum against many internal and external parasites, kills adult fleas, kills some ectoparasitic mites (*Sarcoptes, Notoedres, Cheyletiella, Otodectes*), ease of application,
Disadvantages – Diminished efficacy after bathing or swimming, application site reactions?
Bottom-line – Good product for tick control

Amitraz- containing collars – (Preventic®, Virbac), dog only product
Advantages – Detaches and kills ticks, residual activity for 3 months
Disadvantages – Dog only product
Bottom-line – Good product for tick control

Metaflumizone & Amitraz spot-on preparation (ProMeris Duo™ for dogs, Fort Dodge; not yet available in US
Advantages – Kills ticks, also kills/debilitates adult fleas on contact, ease of application
Disadvantages – Dog only product, diminished efficacy after bathing or swimming?, application site reactions?
Bottom-line – Currently not available in the US

Figure 3. Modern Contagious Acarid Control Products

Selamectin (Revolution® [USA]; Stronghold® [Europe], Pfizer)
Selamectin is used for mite infestations most commonly at label dosages every 2 weeks for a minimum of 3 applications.

Advantages – Kills all 3 ectoparasitic mites, approved for use on dogs and cats, label claims, ease of application, and kills adult fleas and ticks, also broad spectrum against many internal and external parasites
Disadvantages – None
Bottom-line – Good product to treat small animal contagious acariasis

Ivermectin (Ivomec®, Merial; DVMectin®, DVM Pharmaceuticals)
Ivermectin (230 µg/kg or 1/10 cc/10 lbs body weight) is given per os for a minimum of four weekly dosages. Certain dog breeds are potentially more sensitive to this drug owing to the MDR1 mutation, which diminishes the efficacy of the blood-brain barrier. At the dosages used for scabies, this problem is of most concern for Collie Dogs and Shetland Sheep Dogs. Serious adverse neurologic reactions have been seen in Collie Dogs, Shetland Sheep Dogs, Border Collies, Australian Shepherds, and, less commonly, a variety of other breeds.

Advantages – Inexpensive, efficacious
Disadvantages – Toxicity in dogs with MDR1 mutation, Ivomec® is a product licensed for use in cows
Bottom-line – Efficacious product to treat small animal acariasis

Milbemycin oxime (Interceptor®, Novartis Animal Health)
Milbemycin, another avermectin, is also efficacious in treating acariasis. Recommended dosages vary from 1x to 2x the monthly heartworm dose given once weekly for four weeks. Milbemycin may be a 'safer' avermectin than ivermectin, but caution should still be exercised in at-risk breeds.

Advantages – Efficacious, licensed for use in dogs, more safe than ivermectin.
Disadvantages – Toxicity in dogs with MDR1 mutation
Bottom-line – Efficacious product to treat small animal acariasis

***Imidacloprid & Moxidectin* (Advantage Multi®, Bayer; Europe – Advocate®, Bayer)**

Advantages – Ear mites, sarcoptic acariasis?, other contagious mites?, approved for use on dogs and cats, also kills fleas
Disadvantages – Diminished efficacy after bathing or swimming?, does not have activity against ticks, application site reactions?
Bottom-line – New product to treat small animal contagious acariasis?

Amitraz (Mitaban®, Pharmacia & UpJohn)
Amitraz is an MAO inhibitor and should not be used on dogs or applied by people taking other MAO inhibiting drugs. Amitraz should not be used on cats. Amitraz rinsing should be performed in well-ventilated areas. Rubber gloves should be worn by the applier.

Advantages – Efficacious, licensed for use in dogs
Disadvantages – Greater potential for toxicity
Bottom-line – Other products with equal or greater efficacy have less potential for toxicity

ESTABLISHING THE DIAGNOSIS OF FLEA ALLERGY DERMATITIS & CONVINCING THE OWNER

Peter J. Ihrke, VMD, Diplomate ACVD
School of Veterinary Medicine
University of California, Davis, CA

Pruritus is the predominant clinical sign of allergic skin disease in both the dog and the cat. Pruritus together with associated self-trauma also is the most common reason globally for a dog to be presented to a veterinary hospital. The "Threshold Phenomenon" is important in understanding pruritus. An animal or person may tolerate a certain pruritic load without provoking clinical signs but a minor increase in "pruritic load" may push an animal over the threshold thus initiating pruritus. "Summation of Effect" occurs when additive pruritic stimuli from multiple diseases raises an animal above its individual pruritic threshold. As an example, the pruritus from flea allergy dermatitis, atopic dermatitis, and secondary infections all are additive.

Globally, the most common allergic canine skin diseases are, in frequency of occurrence, flea allergy dermatitis, atopic dermatitis, and food allergy. Flea allergy dermatitis (FAD) is not only the most common skin disease seen in general small animal practice in most countries in the world; it most likely is the most common disease of any organ system seen in small animal practice worldwide. Somewhat surprisingly, flea allergy dermatitis still is seen relatively commonly in university dermatology clinics and dermatology specialty practice worldwide. This occurs despite modern advances in flea control plus the fact that most small animal clinicians are quite cognizant of flea allergy dermatitis and routinely manage dogs and cats with flea allergy dermatitis. Self-referral by the owner (second opinion) or veterinary referral of dogs and cats with flea allergy dermatitis occurs for multiple reasons. Surprisingly, when you suspect flea allergy, your most important task is convincing the owner that you are making the correct diagnosis.

DIFFERENTIATING FAD FROM OTHER ALLERGIES

There are no laboratory tests available that definitively rule in or rule out allergic skin disease. Since flea allergy dermatitis is the most common allergic skin disease, it is logical to rule out flea allergy first by several months of strict flea control. Remember that dogs with one allergic skin disease are more likely to have other allergic skin diseases.

Signalment Predilections

Flea allergy dermatitis can be seen in any breed, but it is more common in "allergic breeds" that commonly develop atopic dermatitis and food allergy. Flea allergy is more common in dogs over 6 months of age. Sex predilections have not been reported.

Speed of Onset

Flea allergy dermatitis usually is of rapid onset. Atopic dermatitis usually is insidious and gradual in onset. Food allergy usually is insidious and gradual in onset, but occasionally may be more rapid in onset.

Seasonality Predilections

Flea allergy dermatitis is contingent on flea availability which depends on weather, seasonal temperature and humidity changes, and severity of winters. Atopic dermatitis commonly may begin seasonally (summer), but annually adds time in the spring and fall and finally becomes year-round. Food allergy should not be seasonal.

REASONS WHY FAD IS SEEN IN DERMATOLOGY SPECIALTY PRACTICE

It seems counterintuitive that FAD is seen commonly in dermatology specialty practice. In the author's opinion, the three most common reasons that this occurs are (1) owner disbelief that flea allergy is the correct diagnosis, (2) owner skepticism that flea allergy is the correct diagnosis based on the failure of past therapy, and (3) veterinary practitioner skepticism that FAD is the correct diagnosis based on past therapeutic failure or the lack of visualization of fleas.

OWNER DISBELIEF IN THE DIAGNOSIS OF FAD

Failures in the management of flea allergy dermatitis correlate strongly with owner disbelief that fleas are the underlying problem. We frequently hear the statement, "My veterinarian believes that the problem is due to fleas but I *know* that it is not!" Reasons for this disbelief include:

1. Fleas not seen by the owner
2. Cultural biases against having ectoparasites – "It is not acceptable for me to have ectoparasites. Therefore it is not acceptable for my dog to have ectoparasites!"
3. The attitude that "How can fleas cause this much trouble?"
4. The thought that "All dogs have fleas."

OWNER OR VETERINARY SKEPTICISM BASED ON THE FAILURE OF PAST THERAPY

We regular hear the following comments from owners: "I am already doing everything that I can to kill fleas!" and "We are already using the latest wonder drugs!". Usually we find multiple errors in their flea control program.

REASONS FOR FAD TREATMENT FAILURE

The most common reasons for therapeutic failure include

1. Failure to treat *all* in-contact animals (the squeaky wheel gets the oil... indoor-outdoor cats, regular animal visitors that are not receiving flea control)
2. Failure to use flea control products properly
3. Failure to maintain consistency in treatment
4. Failure to deal with environmental issues in severe cases
5. Substitution of prescription spot-ons with less expensive, but less effective and less safe 'spot-on' products from pet stores

CLINICAL FEATURES OF FAD THAT MAY BE USEFUL IN CONVINCING THE OWNER

The pruritus seen with FAD is predominantly localized to the caudal half of the dog. FAD has a characteristic distribution pattern with partial bilateral symmetry and lesions involving the dorsal lumbosacral region, tail-base, perineum, and medial and caudal thighs. The lesions of FAD include crusted papules, erythema, and excoriations. Secondary or chronic changes include lichenification, hyperpigmentation, alopecia, fibropruritic nodules, and secondary organism overgrowth or infection. Crusted papules in the umbilical fold, especially in male dogs, are an under-appreciated clinical marker of FAD. Fibropruritic nodules are highly characteristic clinical markers of FAD in dogs predisposed to their development. Secondary bacterial or *Malassezia* overgrowth or infections are underappreciated causes of increased pruritus in all allergic skin diseases including FAD.

TECHNIQUES FOR CONVINCING OWNERS THAT FAD IS THE APPROPRIATE DIAGNOSIS (BACKING INTO THE DIAGNOSIS)

We never begin by simply telling the owner that their dog has FAD. During the time that we are establishing rapport with the owner, taking the history, performing the physical examination, and taking surface cytology specimens and evaluating them microscopically, we draw an imaginary line around the middle of a dog and ask the owner; "Does your dog itch more in front of or behind this line?" (Flea allergy dermatitis is the *only* known canine pruritic skin disease seen consistently with a markedly caudal bilaterally symmetric distribution pattern.)

At that point, we briefly discuss with the owner how a diagnosis is made, mentioning lesions, distribution pattern, frequency of occurrence, and ruling out other diseases. We then define allergy and talk about the three most common allergic skin diseases seen in dogs (atopic dermatitis, food allergy, flea allergy). Within that discussion, we talk about flea allergy being an allergic reaction to proteins in the saliva of the flea and tell them that there are at least four different types of allergic reaction to flea antigen that determine the severity of the allergic response. We also indicate that we tend to see severe flea allergy in well-cared-for animals living in clean environments that have limited exposure to fleas. During this discussion, we describe the distribution pattern of the three common allergic skin diseases and gradually let the owners draw their own conclusions about which pattern their own dog best fits. It also is beneficial to show them how many of the possible reasons for FAD treatment failures were present in their previous overall flea control methods.

The presence of ectoparasites on either humans or animals is a hot-button issue in developed, industrialized countries. People do not consider it appropriate to have ectoparasites either on themselves or on their animals. This cultural bias is pervasive, strong, and not particularly rational. One must find a method of diffusing this cultural bias and the hostility that can come with it. In California, we may say, "Fleas are a way of life in ______. My own dogs acquire fleas if I don't practice strict flea control routinely and consistently." The key is getting the owner to buy into the possibility that their dogs pruritus is due to a severe hypersensitivity to the bites of fleas. Again, this includes showing them the possible reasons for previous treatment failures. We also discuss the importance of ruling out "the most common allergic skin disease" before expensive or time consuming testing. We then offer the owners the alternative of 6 weeks of concerted flea control based on our recommendations. Lastly, if this is not working, our final gambit is *not*, "Trust us". Instead it is "Prove us wrong"!

CHALLENGES IN THE MANAGEMENT OF DEEP PYODERMA

Peter J. Ihrke, VMD, Diplomate ACVD
School of Veterinary Medicine
University of California, Davis, CA

Pyoderma is second most common cause of canine skin disease. In areas of the world that are less favorable to fleas, pyoderma is the most common canine skin disease. We can define pyoderma as a pyogenic or pus-producing bacterial infection of the skin. Dogs seem uniquely susceptible to both single-event pyoderma and recurrent pyoderma. The reasons for this may relate to various host factors that could result in enhanced susceptibility to infection. These factors could include the comparatively thin, compact stratum corneum of dogs, the relative lack of intercellular lipids in the canine stratum corneum, the lack of a lipid-squamous epithelial plug in the entrance of canine hair follicles, and the relatively high pH of canine skin.

The diversity of canine pyoderma is enormous. Classification of pyoderma is most usefully based on depth of bacterial involvement as it provides information on diagnosis, differential diagnosis, likelihood of underlying disease, prognosis, and likely response to therapy. Pyoderma may be *surface*, affecting the stratum corneum and outer epidermis; *superficial,* involving only the epidermis and the epithelial appendages in the dermis; or *deeper*, compromising structures in the dermis and the deep, subjacent fatty tissue. As we gain knowledge about canine skin infections, we realize that most infections seem to be secondary to either underlying disease or other underlying factors that somehow increase the likelihood of infection. Few pyoderma are "primary" and do not have underlying causes or triggers. If underlying causes are not found, it is likely that recurrence will follow seeming cure. This recurrence suggests that the initial infection was not "primary" but more likely was secondary to undiagnosed underlying disease or unrecognized triggering factors. Superficial pyoderma are more common than deep pyoderma. As infection proceeds deeper into hair follicles, follicular rupture leads to a granulomatous foreign body tissue response. Deeper infections require a more aggressive diagnostic and therapeutic approach.

Staphylococcus intermedius is by far the most common pathogen in canine pyoderma. Less commonly, *Staphylococcus aureus* and *Staphylococcus schleiferi* may cause canine skin infection. Gram-negative organisms such as *Proteus* sp., P*seudomonas* sp., and *Escherichia coli* are more likely to be secondary invaders in deep pyoderma. Rarely, *Pseudomonas aeruginosa* and other gram-negative organisms can be the sole pathogen. Unusual staphylococcal infection or gram-negative organisms are more likely to be more resistant to various antibiotics.

MICROBIAL RESISTANCE TO ANTIBIOTICS

Microbial resistance in staphylococci is increasing. **Methicillin resistance** has greatly complicated the use of antibiotics in human medicine. Methicillin resistance is being recognized with increased frequency in veterinary medicine and will have substantial impact on how we manage skin disease caused by staphylococcal species in the future. Methicillin resistance is reported in *Staphylococcus aureus* (hospital acquired or community acquired HA-MRSA & CA-MRSA), *Staphylococcus intermedius* (MRSI), and *Staphylococcus schleiferi* (MRSS).

Empirical treatment of staphylococcal infection has been the norm in veterinary dermatology. Only refractory cases have been cultured routinely. This probably has lead to the lack of identification of methicllin-resistant strains. We may be reaching the day when bacterial culture and sensitivity should be recommended for all pyoderma that have not responded to appropriate initial empirical antibiotic therapy.

Emerging concepts that aid in the understanding and management of deep pyoderma include quorum sensing, biofilms, the mutant selection window hypothesis, and the mutant prevention concentration (MPC).

Quorum sensing is a mechanism by which bacteria produce and secrete various signaling compounds (autoinducers) that bind to receptors on other bacteria and activate transcription of genes. This process is responsible for communal behavior among bacteria and offers clues into the processes of symbiosis, commensalism, and pathogenicity. Unlocking the mechanisms of quorum sensing may offer new methods of controlling infection such as disruption of quorum sensing pathways.

Biofilms are aggregates of organisms that form on interfaces. These aggregates are much more protected from the toxicity of antimicrobials or the host immune response and hence are much more difficult to control. Once established, biofilms initiate a range of surface-associated and diffusible signals, which may moderate the settling behavior of other organisms.

The **mutant selection window hypothesis** states that a "dangerous drug concentration zone" exists and that exposure to antimicrobial concentrations inside this zone confers a survival advantage to organisms having reduced susceptibility. The lower boundary of the selection window is approximately the MIC (mean inhibitory concentration) and the upper boundary is termed the MPC (mutant prevention concentration). When an antibiotic is dosed at the top of the MIC, the first decline in organism concentration corresponds to the MIC of the wild-type bacteria. The following plateau is due to the presence of resistant mutant subpopulations. The second drop in organism recovery arises when the MIC of the least susceptible mutant is reached. This latter value is termed the MPC. Above the MPC, an organism must acquire two concurrent resistance mutations for growth to occur (very rare event). Within the mutant selection window, the range of drug concentrations exert selective pressure on microbial growth and cells that harbor resistance genes grow preferentially. Dosing guided by traditional pharmacodynamics standards places antimicrobial concentrations within the mutant selection window, thus selectively enriching resistant mutant subpopulations.

There is much interest in human medicine on dosing at or above the MPC. Newer drugs with pharmacologic properties that allow safe dosing above the MPC will likely become more important in the management of all infections.

COMMON COMPLICATING FACTORS

Both treatment failure and recurrence of infection are associated with lack of recognition of factors that influence prognosis and complicate management of all pyoderma. The most common complicating factors include inappropriate initial therapy, unidentified coexisting and underlying skin diseases, and external environmental factors such as poor owner compliance.

Inappropriate initial therapy includes errors in antibiotic selection, dosage, and duration of therapy. If cytology shows infection to be due to cocci and antibiotic choice is empiric, an antibiotic must be selected with a known spectrum of activity directed against *Staphylococcus intermedius*. Lack of response should initiate culture and sensitivity. Under-dosing leads to diminished therapeutic efficacy and overdosing is more likely to cause adverse reactions and needlessly increases expense. Under-dosing is common in larger dogs and overdosing is more common in small dogs. Systemic antibiotics should be utilized for a minimum of 3 weeks for superficial and 6 weeks for deep pyoderma. In general, antibiotics should be continued for a minimum of 1 week beyond apparent clinical cure in superficial pyoderma and 3 weeks beyond clinical cure for deep pyoderma.

Unidentified persistent underlying skin diseases that may complicate the initial management of pyoderma or lead to recurrence of infection include non-parasitic allergic skin diseases (canine atopic dermatitis, food allergy), parasitic allergic skin diseases (flea allergy dermatitis, sarcoptic acariasis, cheyletiellosis), demodicosis, endocrine diseases (hypothyroidism, hypergluco-corticoidism—primary or iatrogenic), diseases of cornification ("primary seborrhea"), genodermatoses affecting the hair follicles or adnexa (follicular dysplasia, color dilution alopecia, sebaceous adenitis), other infectious skin diseases (*Malassezia* dermatitis), occult neoplasia (solar-induced squamous cell carcinoma), and immunodeficiency (congenital, acquired).

External environmental factors that influence therapeutic success include owner compliance, loss of drug via vomition, and unexpected drug inactivation. Owner compliance is largely unexplored in veterinary medicine. In human medicine, it has been published that only 40% of prescriptions are even filled and only 40% or less of medication received is taken appropriately! Based on studies performed in human medicine, it is likely that compliance is enhanced when drugs are dispensed that need to be administered only once daily. This may contribute to a perceived enhanced efficacy in once-daily antibiotics such as enrofloxacin, marbofloxacin, cefpodoxime, and ormetoprim-potentiated sulfadimethoxine. Twice-daily products such as cephalexin, lincomycin, and clindamycin also may offer advantages over antibiotics requiring administration three times daily.

The management of deep pyoderma offers additional challenges. Deep follicular inflammation frequently leads to follicular rupture and furunculosis. Granulomatous foreign body response directed against free keratin from the root sheath and hair shaft fosters the scar tissue formation and sequestered pyogranulomas. Consequentially, the dual problems of infection and foreign body granulomas coexist. Unidentified or unsuccessfully managed persistent underlying skin diseases are much more likely to be present with deep pyoderma. Additional challenges include antibiotic dosage problems, the impact of sequestered foci of infection, inactivation of the antibiotic by pus and inflammatory products, and the possibility of unidentified mixed bacterial infection with aerobic or anaerobic organisms.

Unidentified or unsuccessfully managed persistent underlying skin diseases that most commonly complicate the management of canine deep pyoderma include demodicosis, hypothyroidism, iatrogenic hypergluco-corticoidism (especially associated with long-term management of allergic skin diseases), genodermatoses affecting the hair follicles or adnexa such as color dilution alopecia and sebaceous adenitis, occult neoplasia such as solar-induced squamous cell carcinoma, and either congenital or acquired immunodeficiency.

Occult demodicosis is a commonly undiagnosed initiator of deep pyoderma. Unexplained pyoderma in unusual locations such as the head and face should cue the clinician to look for demodicosis. Index of suspicion for demodicosis may be low in small long-hair-coated breeds. Hair loss is not a prime sign of demodicosis in these breeds that have long anagen hair cycles.

Hypothyroidism may allow bacterial infection to invade deeper into the skin. Contributors to immune surveillance deficits such as hypothyroidism should be investigated in any dog with unexplained deep infection or infection that becomes more generalized then most pyoderma.

Iatrogenic hyperglucocorticoidism is a common and subtle occurrence noted in the long-term management of allergic skin diseases and other non cutaneous diseases. All dogs receiving long-term oral or parenteral corticosteroids and small dogs (less than 8 kg.) receiving topical, aural or ophthalmic corticosteroids should be suspected of iatrogenic hyperglucocorticoidism if pyoderma is unexplainably widespread or invades more deeply that expected.

Genodermatoses affecting the hair follicles or adnexa such as color dilution alopecia and sebaceous adenitis are underdiagnosed initiators of deep pyoderma. Any anatomic defect in hair follicles predisposes to both superficial and deep folliculitis. Color dilution alopecia is seen most commonly in blue and fawn Doberman Pinschers but has been reported in many other breeds. Breed predilections for sebaceous adenitis, another follicular genodermatosis, have been noted for Standard Poodles, Samoyeds, Akitas, and Vizslas. The disease also has been reported in other breeds.

Solar-induced skin disease in regions of the world with intense solar exposure is underdiagnosed. It occurs in non-pigmented and lightly haired skin exposed repetitively to excessive ultraviolet light. Affected dogs commonly have a history of sunbathing. Multiple stages of premalignant change (solar keratosis) and malignant transformation to invasive squamous cell carcinoma occur concurrently. Dalmatians, Whippets, Italian Greyhounds, Greyhounds, American Staffordshire Terriers, "Pit Bulls," Bull Terriers, Beagles, and Basset Hounds are at increased risk.

Congenital or acquired immunodeficiency may initiate deep pyoderma or make cure more difficult. Acquired immunodeficiency may be seen in conjunction with underlying diseases such as neoplasia (especially lymphosarcoma) or immunosuppressive therapy.

ANTIBIOTIC THERAPY

Most antibiotic dosages recommended for the treatment of pyoderma are largely empiric. Clinicians commonly use the same dosages of antibiotics for both superficial and deep infection. This can lead to the belief in increased resistance of *S. intermedius*. Flexible dosage recommendations for different infections should lead to greater awareness of under-dosing of dogs with deep pyoderma.

In deep pyoderma, sequestered foci of infection impede antibiotic penetration, and keratin debris from ruptured hair follicles encourages foreign body granulomatous response. Granulomatous inflammation prevents antibiotic access to sites of infection. Antibiotics such as penicillins that require microbial replication for activity are less likely to be effective when necrotic tissue and obstructed drainage routes create conditions that are no longer favorable for bacterial multiplication. Consequently, higher antibiotic dosages are warranted in the management of chronic deep pyoderma.

Unidentified mixed bacterial infection with anaerobic as well as aerobic organisms is largely unexplored in the study of canine pyoderma. Recent data in human medicine suggests that anaerobic bacteria may play a larger roll in deep infections that respond slowly or poorly to antibiotic therapy.

Clinicians confronted with canine deep pyoderma should always ask themselves the question, 'Why?' If an underlying management error or an undiagnosed underlying disease is present, success in managing deep pyoderma is low.

Successful management of all deep pyoderma requires systemic antibiotic therapy. Topical antibacterial shampoo therapy commonly is used as an adjunct in the management of deep pyoderma to speed recovery, improve patient well-being and attitude, encourage owners, and potentially prevent recurrence. Immunomodulatory therapy is used less frequently and usually is an attempt to prevent or diminish the frequency of recurrent superficial infection. Extended regimens of antibiotics are used as a last resort in the management of frustrating recurrent infection.

The basic principles of successful systemic antibiotic therapy including selection of an appropriate antibiotic, the establishment of an optimal dosage, and the maintenance of that dosage for enough time to ensure cure rather than transient remission. Surface lesions in deep pyoderma commonly heal more rapidly than deeper lesions, although sequestered foci of infection may not be visible. Antibiotic selection can either be empiric or based on bacterial culture and susceptibility testing. An antibiotic chosen empirically should have a known spectrum of activity directed against *S. intermedius* and, should not be inactivated by beta-lactamases.

Bactericidal antibiotics are recommended for deep pyoderma and when immunosuppression is confirmed or suspected. Pustules or fistulous tracts should be recultured if *S. intermedius* has not been isolated as the primary pathogen. If multiple isolates are not sensitive to one oral antibiotic, an antibiotic that is effective against *S. intermedius* should be instituted since staphylococci create a tissue milieu favorable to the replication of secondary bacterial invaders.

Antibiotics most likely to be successful in the management of deep pyoderma include cephalexin, enrofloxacin, marbofloxacin, cefpodoxime, clindamycin, oxacillin, and clavulanate-potentiated amoxicillin. More resistant *S. intermedius* and gram-negative isolates are seen more commonly in referral practices than in general practice, and resistant bacterial populations are identified most frequently in deep pyoderma.

Chronic, deep pyoderma requires antibiotic penetration as sequestered foci of infection and scarring prevent antibiotic access to the site of infection. First-generation cephalosporins such as cephalexin have good to very good penetrating ability. Cefpodoxime also offers very good penetration. Uptake of enrofloxacin by macrophages was shown to concentrate that antibiotic at the site of deep granulomatous infection thus leading to potent tissue-penetrating abilities. Similar or even better attributes may apply to other new generation fluoroquinolones that are on the horizon. Fluoroquinolones also offer the advantages of once-daily dosing, activity against both *S. intermedius* and gram-negative secondary invaders, and diminished likelihood of resistance. Once-daily dosing with fluoroquinolones is strongly recommended because the bactericidal effect is concentration rather than time dependent.

ADJUNCTIVE THERAPY

Antibacterial shampoos are used as adjunctive therapy in the management of deep pyoderma. Antibacterial shampoos aid in debridement, encourage drainage, and decrease pain. The mechanisms of action is to decrease surface bacterial counts and to limit bacterial recolonization, hopefully diminishing the likelihood of recurrent infections. Improvement in patient attitude and owner encouragement are additional benefits. Antibacterial shampoos contain benzoyl peroxide, benzoyl peroxide and sulfur, chlorhexidine, ethyl lactate, or triclosan. Twice-weekly antibacterial shampoos are the most common recommendation. More aggressive topical therapy is beneficial for the management of deep pyoderma. After clipping, dogs benefit from daily antibacterial shampoos or twice-daily whirlpools. Chlorhexidine is added to warm water. Although labor intensive, whirlpools remain an under-employed but highly beneficial modality of topical therapy for deep pyoderma.

All dogs with pyoderma should be re-evaluated within 2 to 3 weeks. If substantial improvement is not noted, the clinician should consider factors that may have complicated management. Owner compliance to the appropriate dosage and drug loss through vomiting, inactivation by food, or malabsorption are common reasons for failure. Referral to a veterinary dermatologist should be considered each time that clinical failure occurs.

DIAGNOSIS AND TREATMENT OF MANGE

Ralf S. Mueller, DVM, PhD, FACVSc
Diplomate ACVD and ECVD
Faculty of Veterinary Medicine
Ludwig Maximilian University Munich, Germany

The diagnosis of skin disease is often difficult due to the similarity of clinical signs of many dermatoses. A thorough history can be extremely helpful in establishing a diagnosis in veterinary dermatology. Breed predispositions exist for canine demodicosis, young dogs tend to present with ectoparasites more commonly, acute onset of pruritus is frequently seen with scabies, some mites such as ear mites, *Sarcoptes* and Cheyletiella are contagious, the latter two may affect owners as well, and so on. Lesion localization often also gives clinical clues (Table 1).

The primary lesion of canine demodicosis is a follicular papule or pustule (for which there are only two main differentials, bacterial folliculitis and dermatophytosis). Scabies typically presents with nonfollicular papules, cheyletiellosis typically with scaly dermatitis. Ear mites can often be seen with otoscopic examination; the copious coffee-ground debris is classic and can be scooped up and evaluated in mineral oil under the microscope.

DIAGNOSTIC TESTS FOR ECTOPARASITES IN SMALL ANIMAL PRACTICE

Superficial skin scrapings are taken from large surface areas, usually to detect *Sarcoptes* or *Cheyletiella*. Elbows, hocks, ear margins and the abdomen are commonly scraped for *Sarcoptes* mites, the dorsal trunk for *Cheyletiella* mites. Scrapings are performed in the direction of hair growth; 50% of scabies cases may be negative on several scrapings. One mite or egg is diagnostic. It is important to scrape over a large area and in hairy dogs this may be easier if the hair is clipped away first. I use scissors to remove the hair and select non-excoriated sites preferably with scale and papules as the lesions. Mineral oil is then applied directly to the affected skin, gently scraped off the surface, put on a slide, a cover slip is applied and the sample is evaluated microscopically. This technique produces more slides to evaluate, but seems to have a higher diagnostic efficacy.

Deep skin scrapings are performed to detect *Demodex* mites. It is useful to squeeze the skin prior to the scraping in an attempt to push the mites out from the depths of the follicles. A blade covered with mineral oil should be used in the direction of hair growth until capillary bleeding is observed. More than one mite is diagnostic. When evaluating *Demodex* scrapings it is important to assess **and to record** both the site of scraping and the relative numbers of adults, larvae / nymphs and eggs. In subsequent visits assessment of response to therapy relies on the comparison of such numbers, I routinely repeat scrape the same sites on a monthly basis when monitoring my demodicosis cases.

Trichograms or hair plucks may render skin scrapings unnecessary in areas that are difficult to scrape such as the eye lids, periocular area, muzzle or feet. A forceps is used to pluck hairs in a partially alopecic area. The hairs are then placed onto a slide and evaluated under low power. If *Demodex* mites are found, skin scrapings are not necessary. This is particularly useful when sites close to the eyes are affected or the lesions are very painful.

Tape preparation is a direct impression technique using clear sticky tape to collect debris from the surface of the skin. The tape is pressed several times sticky side down onto the skin. Next, it is pressed (also sticky side down) onto a slide. The tape serves as its own cover slip. This technique is especially useful for *Cheyletiella* mites, short-bodied *Demodex* mites and occasionally even *Sarcoptes* mites, as a larger surface area can be sampled very quickly.

Table 1. Localization of Lesions and/or Pruritus of Various Skin Diseases

Localization of Lesions and/or Pruritus	Common Underlying Diseases
Otitis externa	Atopy, adverse food reaction, endocrine diseases **Ear mites** Secondary infections
Pinnae	Atopy, adverse food reaction **Scabies** Vasculitis, pemphigus
Head/face	**Demodicosis** Atopy, adverse food reaction *Microsporum gypseum* Insect allergies
Paws	**Demodicosis** Atopy, adverse food reaction Malassezia dermatitis Pemphigus

SCABIES

Scabies is a contagious disease caused by *Sarcoptes scabiei* var. *canis* in dogs and by *Notoedres cati* in the cat. The mite does not survive off the host for very long periods of time. Clinically, scabies is characterized by tremendous pruritus. Papules, scales and crusts develop at affected sites, typically the elbows, hocks, face and pinnae in the dog and the face, ears and neck in the cat. Any pruritic dog or cat could possibly be infested with *Sarcoptes scabiei* or *Notoedres cati* respectively, particularly if the pruritus was of sudden onset or if pinnae, ventrum and elbows are pruritic. Negative superficial skin scrapings do not rule out scabies, thus trial treatment is indicated in any patient with suspected scabies irrespective of negative skin scrapings. In Europe, where a highly sensitive and specific serum test is available, trial therapy still holds an important place in the diagnosis of scabies, as the tested anti-scabies antibodies take several weeks to reach diagnostic concentrations.

EAR MITES

These are large, white and freely moving mites with four pairs of legs extending beyond the body margin (except the rudimentary fourth pair of the female). The mites feed on epidermal debris and tissue fluid from the superficial epidermis. They cause intense irritation and thick reddish brown crusts in the ears of dogs and cats. Mites are commonly found on other areas of the body, especially the neck, rump and tail. The parasites are highly contagious. Infestations of cats vary from country to country with values as low as 3.5% in Australia and as high as 75% in the States.

CHEYLETIELLOSIS

Cheyletiella ("Walking Dandruff") are large mites (385 µm) that affect cats (*C. blakei*), dogs (*C. yasguri*), rabbits (*C. parasitovorax*) and humans (transiently affected by *C. yasguri* or *blakei*). The yellowish adult mites move rapidly in the stratum corneum but do not burrow. They live on tissue fluid released when they periodically pierce the skin. The ova are smaller than louse nits and are attached to hairs by fine fibrillar strands (not cemented firmly to the hairs as nits). The clinical course in small animals is chronic and typically relatively mild, but may be severe and generalized in 2- to 8-week old puppies. Older individuals may become asymptomatic carriers. Frequently scaling is the only change (due to mites and keratin scales) with mild to no pruritus noted. Cats may develop widespread papulocrustous eruptions and severe pruritus in some cases.

Treatment of Superficial Mites

- Selamectin is a spot on registered for the treatment of scabies and ear mites in many countries. It also has been shown to be effective against cheyletiellosis. I use it every 2 weeks for 3 treatments.
- Moxidectin is available as a spot-on registered for the treatment of canine scabies as well.
- Topical treatments include lime sulfur dips, amitraz, ivermectin and other antiparasitic rinses. They are used weekly for 4 weeks.
- Systemic therapy may be undertaken with ivermectin or milbemycin. The routine protocol for a dog which has never previously been treated with ivermectin before, is a slow increase from 50 µg/kg on day 1 to 100 µg/kg on day 2 to 150 µg/kg on day 3 to 300 µg/kg on day 4. The owners are carefully educated to the above mentioned side effects. If any signs of ataxia or tremors occur, administration of the drug must be discontinued immediately. Once the maintenance dose is reached, we continue that dose once weekly for 3 more weeks in suspected or proven cases with scabies, cheyletiellosis or infestations with *Otodectes cynotis*. Giving milbemycin oxime at 2 mg/kg twice weekly for 3 to 4 weeks has also proven a very safe, easy and successful treatment protocol for canine scabies.
- All animals in contact with the patient need to be treated as well!
- Initial deterioration during the first days of treatment may occur and may be treated with glucocorticoids daily for 3 to 4 days at up to 1 mg/kg body weight.

DEMODICOSIS

Demodex canis is an obligate parasite of the dog and low numbers of mites are part of the normal cutaneous fauna. The life cycle involves fusiform eggs hatching into six-legged larvae, molting into eight-legged nymphs and finally maturing into adults. In the dog, *Demodex canis* is the most commonly recognized mite, but a short-bodied and a long-bodied *Demodex* species have also been described. When considering the pathogenesis of demodicosis in dogs, it is important to distinguish between juvenile onset and adult onset generalized disease. In the former, certain breeds are at increased risk. Analysis from two kennels suggested an autosomal recessive mode of inheritance. Other predisposing factors mentioned in the literature include short hair, poor nutrition, stress, estrus, endoparasites, and debilitating disease. Adult-onset demodicosis can be triggered by drugs or diseases which have altered the immune response. Hypothyroidism, hyperadrenocorticism, leishmaniasis, glucocorticoid therapy, neoplasias or chemotherapy have all been reported in dogs with adult-onset demodicosis, although idiopathic adult-onset demodicosis occurs. In cats, demodicosis is typically due to an underlying systemic disease!

Clinically, canine demodicosis is characterized initially by follicular papules. However, erythema, comedones, pustules and crusting all may occur and any dog with lesional skin disease should be scraped for demodicosis. Lesions can occur anywhere on the body, although the face and feet are mot commonly affected. The treatment of generalised demodicosis is outlined below. Lime sulfur rinses (2%) weekly for 4 to 8 weeks are recommended for the treatment of feline demodicosis.

Amitraz is effective against demodicosis, scabies, *Cheyletiella* spp, and *Otodectes cynotis*. The adverse reactions associated with amitraz administration or application are sedation, bradycardia, hypothermia, hypotension, bloat, polyuria, vomiting and hyperglycemia. Clipping the entire dog is essential to allow better contact of amitraz with the skin. All crusts should be removed (preferably by shampooing with an antibacterial follicular flushing agent such as benzoyl peroxide). The dog has to be dry completely (2–8 hours), before being sponged with amitraz. The person applying the treatment should wear protective gloves and work in a well-ventilated area. At my clinic, owners with asthma are advised to find somebody else for the rinses. The dog should stand in a tub with its feet in the amitraz solution to allow soaking of the often extensively affected feet. Amitraz causes a transitory sedative effect for 12 to 24 hours. Concentration of the drug and frequency of application influences the response rate. I use a concentration of 600 ppm once weekly. For pododermatitis and otitis externa, a mixture of 1 mL of amitraz with 30 mL of mineral oil can be used topically on a daily basis. Treated dogs should not get wet or be washed and should avoid contact with water or wet grass.

Ivermectin orally at 300 to 500 µg/kg daily is used in the treatment of demodicosis and scabies with good success. It must not be used in Collies and Old English Sheep dogs, as it commonly causes adverse reactions in these breeds. They include ataxia, mydriasis, tremors, stupor, salivation, bradycardia and respiratory arrest. In my practice I have seen other breeds affected as well showing ataxia and tremors at lower doses. Thus, the routine protocol for a dog that did not receive ivermectin previously, is a slow increase from 50 to 100 µg/kg to 150 to 300 µg/kg on subsequent doses every day. The owners are avised to monitor the animal carefully during that time for the above mentioned side effects. If any signs of ataxia or tremors occur, administration of the drug must be discontinued immediately. Once the maintenance dose is reached, demodectic patients receive that dose once daily until 4 weeks after the second consecutive negative monthly skin scraping.

Moxidectin is another milbemycin that was evaluated for the therapy of canine generalized demodicosis. Three studies have evaluated moxidectin at 200 to 400 µg/kg/day orally, two of which employed the initial gradual dose increase advocated for ivermectin. Reported side effects were ataxia, lethargy, inappetence and vomition. As moxidectin is a macrocyclic lactone and has a similar mode of action to the other drugs in this group, the success rate and rare adverse effects are not surprising. However, more studies with longer follow-up period periods are needed to identify potential benefits and disadvantages of this drug.

A SYSTEMATIC REVIEW OF INTERVENTIONS FOR CANINE ATOPIC DERMATITIS

Ralf S. Mueller, DVM, PhD, FACVSc
Diplomate ACVD and ECVD
Faculty of Veterinary Medicine
Ludwig Maximilian University Munich, Germany

Canine atopic dermatitis (CAD) is one of the more common skin diseases in small animal practice and in many respects similar to the frequently diagnosed atopic dermatitis in humans. A number of drugs have been reported as successful treatment for this disease in human and veterinary medicine, but in contrast to the human side, many treatment modalities have not been evaluated carefully with randomized controlled trials (RCT) in the veterinary field. A recent paper has attempted to systematically review most therapies in an evidence-based fashion.[1] This article will summarize the results of therapeutic trials using glucocorticoids, calcineurin inhibitors, antihistamines, fatty acids, leukotriene and phosphodiesterase inhibitors, prostaglandin analogues, allergen-specific immunotherapy (ASIT) and topical therapy for canine atopic dermatitis.

It has to be noted that validated clinical scoring systems for CAD were not developed until recently and have only been used in the last decade. In addition, evaluation of pruritus is difficult and subjective. Good validated scoring systems are not available at this point. It is hoped that the International Task Force of Canine Atopic Dermatitis will develop recommendations for such validated scoring systems in the next few years.

GLUCOCORTICOIDS

There is only one RCT evaluating topical 0.015% triamcinolone acetonide. After 4 weeks, clinician-assessed overall scores and owner-assessed pruritus scores decreased by 67% and significantly more than with placebo treatment. Adverse effects were lower than in the placebo group. Oral glucocortocoids typically were evaluated as standard-of-care controls in RCTs for comparison with other interventions and methylprednisolone, prednisone and prednisolone at 0.4 to 1 mg/kg/day were most commonly used. At the end of 4 to 16 weeks of treatment, lesion scores were reduced from 45% to 83% and pruritus by 33% to 81%. Adverse effects included polyphagia, polyuria/polydipsia (PU/PD), weight gain and/or intermittend GI signs. There is *good evidence for high efficacy* of oral and topical glucocorticoids and low harm of short term treatment. The benefit of long-term treatment with glucocorticoids must be weighed against the risk of adverse drug effects impacting on health and quality of life.

CALCINEURIN INHIBITORS

Oral cyclosporine is probably the most thoroughly evaluated drug for the treatment of canine atopic dermatitis. Three large blinded trials have been conducted with several hundred dogs. Cyclosporine at 5 mg/kg/day was found to be equally effective as prednisolone and methylprednisolone. After 6 weeks of treatment the reduction of clinician-graded lesion scores was 52% to 67%. Similarly, decrease of owner-assessed pruritus was 36% to 100%. Vomiting and diarrhea were the most commonly seen adverse effects and seen in 14% to 42% but were mostly mild to moderate and a reason for cessation of therapy in less than 1% of the patients. Papillomatous eruptions and gingival hyperplasia were also seen occasionally. The trials provided *good evidence for high efficacy* of oral cyclosporine in canine atopic dermatitis and are documented in a recent meta-analysis. However, the long term safety of cyclosporine in dogs is not known beyond the safety studies of cyclosporine treatment for one year in Beagle dogs.

Topical calcineurin inhibitors are registered for the treatment of human atopic dermatitis. Tacrolimus lotion was evaluated in several studies. At a concentration of 0.1%, it decreased clinician–assessed lesion scores and owner-assessed pruritus scores of localized atopic dermatitis by 60% to 63% and 58%, respectively, after 4 to 6 weeks of once to twice daily therapy. The only adverse effect seen in the studies using tacrolimus was mild and transient irritation at the site of application. These trials provide *good evidence for medium efficacy* of 1% tacrolimus in CAD.

HISTAMINE RECEPTOR ANTAGONISTS

Most studies evaluating first-generation, sedating type 1 histamine receptor antagonists were neither blinded nor randomized or controlled. They provide conflicting evidence of benefit for chlorpheniramine, clemastine, diphenhydramine, hydroxyzine, promethazine and trimeprazine for treatment of CAD. However, adverse effects are rare and consist most commonly of drowsiness. One blinded RCT provided *fair evidence of medium efficacy* of a combination of hydroxyzine (25–100 mg/dog/day) and chlorpheniramine (1–4 mg/kg/day). An improvement of more than 50% in lesional scores was seen in 18% and of pruritus scores in 30% of the dogs, investigators judged the treatment satisfactory in 24% of the dogs. This combination product is the first choice treatment with type 1 histamine receptor antagonists in our clinic.

Second-generation low-sedation type-1 histamine receptor antagonists such as loratidine and astemizole did not show efficacy in several studies, terfenadine showed conflicting results. Both terfinadine and astemizole can induce cardiac arrhythmias in dogs. Considering the concurrently demonstrated lack of efficacy, these antihistamines should be used cautiously for the therapy of CAD. Oxatomide at 1 to 2 mg/kg/day did show medium efficacy in several trials with 20% to 50% of patients exhibiting a satisfactory control of pruritus. Adverse effects were only mild and transient and consisted most commonly of increased appetite.

These trials provide *fair evidence of no or low efficacy* of the first-generation sedating type-1 histamine receptor antagonists chlorpheniramine, pheniramine, diphenhydramine, hydroxyzine, promethazine and trimeprazine for treatment of CAD, *fair evidence of* *medium efficacy* of treatment of canine AD with oxatomide and with a combination of chlorpheniramine and hydroxyzine. As a group, there is conflictual evidence of benefit of type-1 histamine receptor antagonists for treatment of canine AD.

POLYUNSATURATED FATTY ACIDS

There are a number of studies evaluating polyunsaturated fatty acids (PUFA) for the treatment of canine atopic dermatitis. Omega-6, omega 3 fatty acids or or a combination thereof were evaluated. In double-blinded, placebo-controlled studies, the difference between placebo and PUFA supplementation was typically significant, between 25% and 40% of patients responded favorably in the treatment groups. There is also evidence that concurrent administration of PUFAs decreases the requirements for glucocortocoids in atopic patients and that a combination of antihistamines and PUFAs is more effective than either therapy alone. Adverse effects of PUFA therapy were mild and typically consisted of diarrhea. There is *good evidence for moderate efficacy* of PUFA therapy in canine atopic dermatitis.

PHOSPODIESTERASE INHIBITORS

Papaverine, arophylline and pentoxifylline were all evaluated. Papaverine at 150 to 300 mg/dog twice daily did not lead to satisfactory control of pruritus in an open, nonblinded, non-randomised trial. In a randomized, controlled trial, arophylline at 1 mg/kg twice daily showed a fair efficacy with 50% reduction in lesional and 67% reduction in pruritus scores. However, vomiting was seen in 7/10 dogs and lethargy and polyuria in one dog each, 4 dogs treated with this drug did not complete the trial due to severe vomiting. Pentoxifylline at 10 mg/kg twice daily for 4 weeks was found to be more effective than placebo, it reduced erythema scores by 30% and pruritus scores by 35%. Clinical adverse effects were not noticed in this trial. Due to either inefficacy or an unacceptable rate of adverse effects, papaverine and arophylline cannot be recommended for the treatment of canine atopic dermatitis. There is *fair evidence for moderate efficacy* of pentoxifylline.

LEUKOTRIENE INHIBITORS

Leukotriene inhibitors have been evaluated for the treatment of canine atopic dermatitis in four trials, three of which were RCTs. Zafirlukast did show sustained fair to good reduction of pruritus in 2/18 dogs. Zileutin treatment did lead to a pruritus reduction of >50% in 3/9 (33%) of the dogs, erythema, but not pruritus scores were significantly lower that those of placebo treatment. In two other trials with leukotriene antagonists, no difference in lesion and pruritus scores between the drug and placebo was found. Zafirlukast caused vomition in two dogs, adverse effects were not seen with Zileutin. The trials provided *good evidence for no or very low efficacy* of leukotriene synthesis inhibitors or receptor antagonists for alleviation of clinical signs in dogs with CAD.

PROSTAGLANDIN ANALOGUES

A 4-week open study and a 3-week placebo-controlled blinded RCT evaluated the efficacy of treatment with the PGE_1 analog misoprostol. In both trials the clinician-assessed lesional scores and the owner-graded pruritus values were significantly lower at the end of the study compared to those at baseline. At the end of the RCT, and compared with subjects receiving placebo, dogs treated with misoprostol exhibited significantly higher percentage reduction from baseline of pruritus scores, but not of lesional values. Adverse drug effects were mild and intermittent and consisted of vomiting or diarrhea. These studies provide *fair evidence of medium efficacy* of the prostaglandin analog misoprostol (5 µg/kg three times daily for up to six weeks) to treat dogs with AD. Aspirin was evaluated in an open clinical trial of 45 dogs and achieved partial or complete remission of pruritus in only a small percentage of dogs. There is *limited evidence of no efficacy* of the prostaglandin inhibitor aspirin for treatment of this disease.

ALLERGEN-SPECIFIC IMMUNOTHERAPY

Although there are a number of studies evaluating the effect of ASIT on canine atopic dermatitis, most studies were retrospective and thus neither blinded nor controlled. In addition, in many studies follow-up times were short. Most of these studies report excellent efficacy in approximately 20% of the patients and good response in an additional 25% to 45%. The first prospective double-blinded, placebo-controlled study of ASIT in veterinary medicine reported 59% of 27 patients with significant improvement, but improvement was not evaluated with detailed clinical and pruritus scores used in more recent studies evaluating therapies for canine atopic dermatitis. Two years ago, a double-blinded RCT comparing conventional with rush immunotherapy found significant improvement in pruritus, medication and clinical scores after 12 months of immunotherapy, there was no significant improvement with conventional immunotherapy. As ASIT is a long-term therapy and many patients are in need of additional medication and as each patient has its unique set of allergens as well as possibly a unique protocol of administration to maximize success rate, scientific evaluation of ASIT is difficult. However, at this point, the numerous studies can be considered *fair evidence for moderate efficacy* of ASIT in the treatment of CAD.

TOPICAL ANTIPRURITIC DRUGS

An open four week trial evaluated two commercially available formulations of pramoxine-containing cream rinses. Overall, a good reduction (51% to 75%) in pruritus for 48 hours was assessed subjectively by the owners for seven dogs (41%). This provides *limited evidence of medium efficacy* of pramoxine. Another RCT compared the efficacy of whirl pool therapy with an antipruritic shampoo, conventional shampoo therapy and whirlpooling in water. Dogs improved significantly more with conventional shampooing and with shampoo therapy in the whirlpool compared to the control group, but there was no difference between the two modes of therapy. More dogs improved by 50% and 90%, respectively in the whirlpool group compared with the conventional shampoo treatment, but the difference was not statistically significant.

MISCELLANEOUS DRUGS

Taken together, three open studies provided *limited evidence of no efficacy* of the immune-modulating antibiotics erythromycin, doxycycline and tetracycline-niacinamide for pruritus reduction in dogs with canine AD. Of note is that such antibiotics could be considered for treatment of cutaneous bacterial infections that are often present during the course of canine AD. Three randomized trials provide *conflicting evidence of no or low efficacy* of the serotonin and histamine antagonist cyproheptadine. Administration of this drug commonly triggers an increase in appetite. Two open studies reported *limited evidence of variable efficacy* of the tricyclic antidepressants doxepin and amitriptyline. One trial provides *limited evidence of low efficacy* of Chinese herbal therapy. There is *limited evidence of no or low efficacy* of commercial homeopathic complex remedy, ascorbic acid, AHR-13268 and tranilast.

SUMMARY

Although there is a need for randomized controlled trials to evaluate many drugs currently used or under investigation for the treatment of canine atopic dermatitis, published studies allow some conclusions. Currently, there is good evidence for a high efficacy of glucocorticoids such as prednisolone or methylprednisolone at a dose of 0.5 to 1 mg/kg every 24 to 48 hours and cyclosporine at a dose of 5 mg/kg every 24 to 48 hours and a medium efficacy of polyunsaturated fatty acids and topical tacrolimus at 0.1% daily. Fair evidence can be provided for medium efficacy of allergen-specific immunotherapy, pentoxifylline at 10 to 15 mg/kg every 12 hours, misoprostol at 5 µg/kg q 8 hours, oxatomide at 1 to 2 mg/kg/day and a combination of chlorpheniramine and hydroxyzine at a dose of 1 to 4 and 25 to 100 mg/dog/day, respectively. For all other drugs evaluated there was either not enough evidence provided, no sufficient treatment success was found, or adverse effects were to severe to recommend them routinely for the treatment of canine atopic dermatitis.

ARE STORAGE MITE ALLERGENS RELEVANT?

Storage mite–specific immunoglobulin E (IgE) is frequently identified in dogs with atopic dermatitis. Similarly, atopic patients frequently show positive reactions to various storage mites on intradermal testing. The most commonly tested storage mites are *Acarus siro* (flour mite), *Tyrophagus putrescentiae* (mould mite), *Lepidoglyphus destructor* (hay mite), and *Glycyphagus domesticus*. However, it has been shown that normal dogs also react to storage mites, and that there is no difference in frequency of positive reactions between normal and atopic dogs. Similarly, it has been shown that cross-reactivity between dust mites and storage mites exists. Furthermore, two studies failed to identify storage mites in commercial dog food kept in normal households. So should we really include these storage mites antigens in allergen-specific immunotherapy extracts or should we categorically ignore the results of skin and serum testing regarding storage mites?

WHAT'S THE BEST WAY TO DO A HYPOALLERGENIC DIET TRIAL?

A diet trial is the best (actually, the only) way to diagnose food sensitivity in pets. There is no conclusive evidence that either a home-cooked diet, a commercial novel-protein diet, or a commercial hydrolyzed diet is better to use as a trial diet...use the one the pet will eat! The far more important factor is *client compliance* – that the client be VERY STRICT, which is nowadays much easier with the advent of a variety of hypoallergenic treats, snacks, and chews. Is table food permitted at all, like carrot sticks or fruit? Some authorities have recommended up to a 3-month trial period. Is this really necessary, or will a shorter period suffice? Also, is it permissible to concurrently use oral corticosteroids for the first couple of weeks of a hypoallergenic diet trial?

HOW DO I DEAL WITH RECURRENT PYODERMA IN A DOG WITH ATOPIC DERMATITIS?

Secondary bacterial infections, particularly with staphylococci, are common in dogs and humans with atopic dermatitis. Increased bacterial adhesion to corneocytes of atopic dogs and humans has been demonstrated, and clinical improvement of patients with secondary infections following oral antibiotic therapy as well as topical antimicrobial agents has been shown in a number of studies. However, chronic use of antimicrobial agents frequently meets owner resistance. Multi-drug resistant staphylococci are becoming a problem both in veterinary and human medicine, and resistant strains develop more easily with chronic use of antibiotics. Furthermore, in humans and dogs, individual patients with flaring infections may respond to aggressive anti-inflammatory therapy, without use of antibiotics. So, if a patient with chronic allergies is repeatedly presented with clinical and cytologic evidence of bacterial pyoderma, should we use antibiotic treatment long term, begin pulse therapy with antibiotics, or what other means should we consider?

WHY CAN'T I GET RID OF THIS DOG'S CHRONIC EAR DISEASE?

Recurrent or chronic otitis externa is a common and frustrating problem. One common reason why ear disease becomes recurrent is that multiple bacterial organisms are present in the infection, including multiple strains of difficult organisms such as *Pseudomonas*, and some of these are highly antibiotic resistant. A second reason is the presence of occlusive disease—narrowing or blockage in the ear canal by edema, hypertrophy, scarring, calcification, or masses. The presence of otitis media may also lead to lack of response to conservative treatment; this is difficult to assess without imaging procedures. Finally, bilateral chronic ear disease often occurs due to presence of an underlying inflammatory skin/ear disorder such as atopic dermatitis or primary seborrhea. Failure to consider each of these reasons for "chronic ears" will typically result in treatment failure.

HOW FAR DO I GO IN DIAGNOSTIC EVALUATION OF A DOG WITH ADULT-ONSED DEMODICOSIS?

Generalized demodicosis is a relatively common disease in veterinary dermatology. In young dogs, it is considered a genetically determined problem that allows abnormal proliferation of *Demodex* mites, a normal part of the cutaneous microfauna. In adult dogs, a suppressed immune system is often responsible. This may be reportedly due most commonly to administration of immunosuppressive drugs such as glucocorticoids, but hyperadrenocorticism, hypothyroidism and internal neoplasia have also been associated with adult onset demodicosis. In a dog with no history of drug administration and with no clinical signs of hormonal or neoplastic disease, a diagnostic workup for these diseases is indicated. How far should we go with such a workup? Is a biochemistry panel and complete blood count sufficient, should we proceed to determination of urine cortisol-creatinine ratios and thyroid hormone concentrations, possibly add ultrasounds, radiographs and lymph node aspirates or even routinely perform endocrine function testing and CT/MRI in these patients?

WHICH ALLERGY TEST IS THE BEST?

In the past, veterinary dermatologists have preached that serum-based "allergy tests" (allergen-specific IgE determinations) are unreliable, and that intradermal testing (IDT) is the only really reliable method for determining allergic sensitivities. Is this still true? Is referral for IDT still the best option, or should we consider use of the serum tests? Which serum test is the best? What are the important factors to consider when we use a serum allergy test?

SHAVE BIOPSIES OF THE PINNA – AN EASY AND COSMETICALLY APEALING TECHNIQUE

Ralf S. Mueller, Dr.med.vet., Diplomate ACVD and ECVD, FACVSc
Faculty of Veterinary Medicine
Ludwig Maximilian University, Munich, Germany

Skin biopsy is a frequently used diagnostic procedure in veterinary dermatology. This is the diagnostic test of choice, particularly for immune-mediated and neoplastic disease. However, the punch biopsy, an easy technique on most parts of the body, is more difficult on the pinna. Similarly, wedge biopsies are not ideal on ears. Cartilage is found directly under a very thin dermis and the panniculus is absent on the pinnae. Punch and wedge biopsies lead to hemorrhage and suturing may lead to permanent change in the shape of the pinna. In addition, cartilage may inadvertently be damaged. Many diseases of the pinnae such as lupus erythematosus, diseases of the pemphigus complex, and infections with bacteria or yeast are diseases of the epidermis or dermo-epidermal junction. In these cases, deep biopsies showing panniculus, cartilage, or deep dermis are not necessarily needed. A shave biopsy is the technique of choice in these patients.

TECHNIQUE

This technique is to be performed under general anesthesia. However, as it is a fast procedure, inhalation anesthesia is not necessarily needed; injection anesthesia and analgesia will typically suffice. If the outside of the pinna is to be biopsied, it should be gently clipped with scissors. On the inside of the pinnae, clipping is usually not needed. A scalpel blade or shaving blade is held in one hand, the pinna is bent over the index finger of the other hand. On the stretched and bent convex surface, the scalpel blade is used to cut into the skin at an angle of approximately 20° until capillary bleeding is observed. At that particular depth the incision is continued parallel to the surface of the skin until a specimen of about 5 x 5 mm (0.25 x 0.25 inches) is obtained. This sliced-out specimen is a very thin piece of skin and needs to be placed with the dermal surface down on a piece of a tongue depressor or a cardboard. In addition, a piece of lens paper may be draped around the specimen and cardboard to ensure that the sample is not separated from the more easily visible base. Placing the thin specimen on a flat surface avoids distortion of the specimen in the formalin and at the same time ensures that the laboratory technician cutting in the biopsy will notice the small sample. The resulting ulceration on the surface of the pinna is dabbed with a silver nitrate stick to stop the hemorrhage. Alternatively pressure can be applied with a cotton swab for 2 to 5 minutes or electrocautery can be used. Suturing is not required and the lesions heal within a few days without any permanent damage. Histopathology will reveal changes of the epidermis and upper dermis, as the depth of the specimen with proper technique will reach the mid-follicular level. Changes on the surface of the skin, such as acantholytic cells in crusting (as seen in pemphigus) or bacterial or yeast colonies, epidermal changes such as intraepidermal pustules or vesicles or a possible interface dermatitis with basal cell vacuolization or apoptosis as seen in lupus may be appreciated. Thus, differentiation of pemphigus and superficial pyoderma from lupus erythematosus is typically possible. However, deep dermal changes such as vasculitis and pathology of the cartilage cannot be evaluated with this technique.

SUMMARY

Shave biopsies are a fast method of acquiring skin specimens to evaluate the epidermis and superficial dermis histologically and are particularly suited for areas of the body such as the pinnae, where suturing is difficult or may lead to permanent changes. They will reveal pathological changes in the epidermis and superficial dermis and are thus typically able to differentiate between infections and autoimmune diseases affecting the upper part of the skin such as pemphigus and lupus erythematosus. Healing of the sampling sites is usually without complications and permanent changes.

CANINE ALOPECIA: WHAT'S NEW

Rod A.W. Rosychuk, DVM, Diplomate ACVIM
College of Veterinary Medicine and Biomedical Sciences
Colorado State University, Ft. Collins, CO

CANINE NON-INFLAMMATORY, NON-PRURITIC ALOPECIAS: DIFFERENTIAL DIAGNOSES

- **"Classic" endocrine alopecias** – Follicles telogenized, atrophic, hairless: hypothyroidism, hyperadrenocorticism, sex hormone imbalances (Sertoli's cell tumor, testicular neoplasia, cystic ovaries, ovarian neoplasia), pituitary dwarfism (growth hormone deficiency).
- **Hair cycle arrest syndromes** – Follicles in catagen or early telogen: Alopecia X (including adrenal sex hormone imblanace, castration responsive alopecia, sex hormone responsive dermatoses, maturity onset growth hormone responsive dermatosis), Siberian Husky follicular dysplasia (possibly), Malamute "Coat Funk" (possibly), post-clipping alopecia, telogen defluxion.
- **Follicular Dysplasia** – Abnormal follicular morphology: cyclic flank alopecia, color dilution alopecia , black hair follicular dysplasia
- **Crossover Syndromes** (hair cycle arrest and follicular dysplasia)? – Alopecias of the Irish Water Spaniel, Chesapeake Bay Retrievers, Portuguese Water Dog
- **Others** – Pattern baldness
- **Others** – Sebaceous adenitis (clinically non-inflammatory), alopecia areata (clinically non-inflammatory)
- **Congenital alopecia**

WHERE ARE WE NOW WITH RESPECT TO UTILIZING SKIN BIOPSIES TO BETTER DIFFERENTIATE THESE PROBLEMS?

Many of the above problems are diagnosed on the basis of history, physical examination (cyclic flank alopecia, pattern baldness), screening laboratory work including complete blood count (CBC), serum chemistry panel and urinalysis and more specific endocrinologic tests (hypothyroidism, hyperadrenocorticism) and/or response to trial therapy (eg, hypothyroidism, Sertoli's cell tumor). Biopsies are most commonly considered once hypothyroidism and hyperadrenocorticism have been ruled out as likely causes of alopecia.

Biopsies: Take samples from areas that are most significantly alopecic; ideally from the more dorsal areas of the thorax, abdomen, lumbar region (assuming affected) because the follicular units (follicles and adnexae are largest here and easiest for a pathologist to assess. In skin over the ventrum, the epidermis tends to be thinner than over the back and sebaceous glands tend to be smaller. These characteristics could mimic endocrine changes. A sample should also be taken from a more normally haired area.

One can mark the sample prior to taking the biopsy, which will allow for better visualization of the entire follicular unit from the epidermis to the deep dermis or subcutis. This is achieved by drawing a line (permanent marker; "sharp" Sharpie pen) along the lay of the hair and then centering the biopsy punch on this. Make it known to the pathologist that you have marked the sample and ask to have it cut in along the line.

CANINE ENDOCRINOPATHIES

Coat Changes Associated with "Classic" Endocrinopathies: Hypothyroidism, Hyperadrenocorticism (Spontaneous and Iatrogenic)

Failure of hair regrowth following clipping; irregular/abnormal shedding cycles; increased loss of hair; in some, may see retention of hair; lightening or "bleaching" of truncal coat color, with a tendency to spare the head and distal extremities (ie, the head and extremities retain their original color); changes in hair texture (coarse or frizzy hair); initial loss of hair over areas of wear (eg, dorsum of tail, axilla, inguinal area) with progression to a more classical bilaterally symmetric truncal alopecia that spares the head and distal extremities.

Skin changes: Cutaneous hyperpigmentation (earliest in areas of alopecia); comedones (most commonly over ventral abdomen); seborrhea (sicca or oleosa); skin thinning/atrophy (hyperadrenocorticism; often seen earliest in areas of previous scarring); skin thickening (hypothyroidism, associated with epidermal thickening and mucin deposition in the dermis). Patients with these endocrinopathies are often prone to recurrent/persistent bacterial pyoderma. These skin/coat changes are non-pruritic, unless complicated by secondary bacterial pyoderma or *Malassezia*. Secondary seborrhea may also potentiate pruritus, but it is usually mild. It is interesting to note that the cutaneous signs associated with hyperadrenocorticism may not all be related to just the overproduction of cortisol in affected individuals. It has been noted that adrenal sex hormones may also be produced in excess quantities in spontaneously Cushingoid patients. In one study of 10 dogs with PDH, elevated sex hormones were noted following ACTH stimulation with the following incidence: androstenedione (5 of 9), DHEAS (2 of 8), progesterone (6/10), 17 hydroxyprogesterone (4 of 10).

HAIR CYCLE ARREST SYNDROMES (PATHOGENESIS UNCLEAR)

Alopecia X (Hair Cycle Arrest)

Alopecia X is typified by hair follicles that are "arrested" in the catagen or telogen stage of the hair follicle cycle. For this reason, the syndrome has also been referred to as "Hair Cycle Arrest." It is most commonly seen in the Nordic breeds or "plush coated" breeds: chow chow, pomerainian, keeshound, samoyed, Siberian husky, Alaskan Malamute, American Eskimo dog and Finnish spitz. The miniature poodle also appears to be predisposed. Other individuals in other breeds may also be affected. Some have suggested that Malamute coat "funk," and follicular dysplasia of the Siberian husky may also fall within this category.

Affected dogs begin to develop hair loss as young, mature individuals, usually at 1 to 3 years of age.

However, older individuals may also develop the syndrome. Although the problem is more common in intact males, both males and females (intact or neutered) may be affected.

Alopecia is truncal, sparing the head and distal extremities. The truncal coat lightens in color, again sparing the head and distal extremities. There may be focal regrowth of hair at sites of trauma

The etiology of alopecia X remains very controversial. Affected individuals often do regrow hair following neutering or the administration of sex hormones, or the administration of sex hormone-altering drugs. Some, but not all affected dogs have been noted to have elevated basal and/or ACTH-stimulated progesterone, 17-hydroxyprogesterone, androstenedione, estradiol, or other sex hormone concentrations. This suggests an abnormality of adrenal sex hormone production. These hormones may have any one of a number of effects in the local metabolism of sex hormones at the follicular level, or on sex hormone receptors. Arguing against the importance of these sex hormones and sex hormone intermediates is the observation that successful treatment with either melatonin or mitotane does not alter sex hormone profiles in affected individuals. In some cases the sex hormone concentrations even worsen with trilostane therapy, in spite of hair re growth. In addition, after stimulating hair regrowth, hormonal therapy may be stopped in some and hair regrowth will continue to persist for many months to years. Spontaneous resolution of the problem has also been noted. It would seem more likely that this may be a primary hair growth disorder: a genetic predisposition to the development of a local defect in the hair growth cycle that may involve local follicular hormonal metabolism abnormalities and/or hormone receptor abnormalities.

The diagnosis is largely by history, physical findings, and rule out (ie, hypothyroidism, hyperadrenocorticism, etc.). Skin biopsies are suggestive, but not confirmatory. Hairs in most affected breeds tend to be in the early phase of telogen (so-called "flame follicles") with the "flame" description related to excessive tricholemmal keratinization. Sebaceous glands tend to be normal to slightly attenuated. In the Pomeranian, it has been noted that "flame" follicles do not tend to be as prominent, and instead, there may be more of a miniaturization of hair follicles. Pomeranians and non-Nordic breeds are also more likely to have dermal atrophy.

It is important to note that once alopecia X is strongly considered as the most likely diagnosis, no further workup may be necessary, especially if the owners are willing to live with an alopecic pet. To date, there are no obvious systemic abnormalities associated with this disease, and there is therefore no need to do further workup and therapy.

In the author's hands, diagnostics from this point are usually based on assessing response to therapy. Neutering is recommended initially. If this fails to be of benefit (or the patient must be left intact), we generally try melatonin for a 3-month period (3–6 mg BID to TID). We treat until maximal response is noted and discontinue the melatonin. Therapy is re instituted if and when signs recur. This protocol has been suggested to circumvent what some have noted as the development of an intolerance to the drug with chronic administration. Melatonin is noted to produce partial or complete coat regrowth in 50% to 60% of cases. Should this fail to be of benefit, we try methyltestosterone therapy (1 mg/kg to a maximum dose of 30 mg, once daily; generally tolerated well, but can cause hepatotoxicity, aggressive behavior and/or seborrhea; recommend a baseline liver profile prior to administration, then 1 and 2 months after initiating therapy). Supplementation is stopped after maximal regrowth is noted.

If melatonin or methyltestosterone fail to be of benefit, then we tend to recommend measuring sex hormones pre and post ACTH stimulation (eg, University of Tennessee sex hormone panel) If abnormalities are noted, there is rational for treating with mitotane (op,DDD; Lysodren) or trilostane.

Mitotane likely benefits affected individuals through its adrenolytic effect on the zona reticularis and fasiculata (from which sex hormones are produced). It may also have direct peripheral effects on follicle function. Induction is usually done at a more conservative dose of 15 to 25 mg/kg PO daily for 5 to 7 days. An ACTH stimulation is performed 24 hours after the induction dose is completed. The goal is to have the pre and post stimulation cortisols within the normal resting range for the laboratory being used (eg, pre and post cortisol should be 3 to 5 µg/dL). If cortisol values are as desired, the patient is placed on the daily induction dose (15–25 mg/kg) divided and given twice weekly. If the values are low, mitotane should be discontinued and started on a maintenance basis once cortisols have returned to the desired range. An ACTH stimulation test is generally performed 4 to 6 weeks after adequate induction, 3 months after this, then every 3 to 6 months thereafter. Consideration should be given to discontinuation of the mitotane therapy once full hair regrowth is noted (some will continue to grow hair for protracted periods of time). Success rates: in one study, 12 of 12 chows were noted to respond, in another study, 4 of 6 dogs were noted to respond.

Trilostane, a drug used to treat hyperadrenocorticism (competitive inhibitor of 13-beta-hydroxysteroid dehydrogenase, which interferes with adrenal steroidogenesis) promotes hair regrowth in non-Cushingoid individuals, but 17-hydroxyprogesterone concentrations consistently go up in treated individuals. Therapy is given daily until maximal regrowth is noted. At that time, consideration should be given to discontinuing the drug and assessing for duration of response (may be long term) or the need to establish a maintenance regimen (eg, two to three treatments weekly). In one study, response was noted in 13 of 16 Pomeranians and 8 of 8 miniature poodles. In another study, 3 of 3 Alaskan Malamutes responded to Trilostane therapy. Trilostane appears to be well tolerated but is expensive and must be ordered from abroad at present. A source (UK) and protocol for use and monitoring (cortisols are monitored by ACTH stimulation) is available at wwwmastermarketing.com.

FOLLICULAR DYSPLASIA

Canine Recurrent Flank Alopecia (Seasonal Flank Alopecia, Canine Idiopathic Cyclic Flank Alopecia, Cyclic Follicular Dysplasia)

These conditions hav a high incidence in Airedale terriers, Boxers, English bulldogs, Schnauzers, Griffon Korthals, Affenpinscher and Bearded Collie (genetic predisposition). Well-demarcated, variably symmetric alopecia and hyperpigmentation are noted over the flanks, lateral thoracoabdominal area, and may involve the dorsal and dorsolateral lumbar region. Episodes of alopecia are often recurrent (ie, hair loss in the fall, only to regrow in the spring or vice versa). The cycle may repeat itself yearly or skip years. It has been hypothesized that the problem may be related to a genetically influenced melatonin deficiency, which may affect the skin either directly or indirectly through melatonin's effects on prolactin, androgens, estrogens, and/or growth hormone. Melatonin can be used to shorten the duration of an alopecic episode or to prevent recurrence. Response to therapy is noted in about 50% to 75% of cases. Dosage is 3–6 mg given BID to TID for 2 months (until hair loss is not noted when expected as the season changes or until good hair regrowth is noted). Therapy is stopped once hair growth has been attained. Therapy is reinstitute for recurrences. A variant of this disease has been noted in the Golden retriever wherein cyclic alopecia is noted to develop over the bridge of the nose.

Color Dilution Alopecia

This condition is seen in the Blue Doberman, Great Dane, whippet, dachshund, standard poodle, chow chow, red and fawn Doberman, and fawn Irish setters. Born with a normal coat; gradually develop alopecia only affecting the color dilute (eg, blue) areas of the coat. In the past, treatments have been largely symptomatic (antiseborrheic shampoos, moisturizers; antibiotics for secondary infections). Oral synthetic retinoids (eg, isotretinoin, acetretin) have been suggested to produce some partial regrowth. More recently, melatonin has been noted to benefit some individuals (hair regrowth); dosage: 3–6 mg BID to TID until maximal response is noted. Response is noted in 30% to 40% of patients.

Follicular Dysplasias?

Other alopecic syndromes which have been thought to be follicular abnormalities +/- adrenal sex hormone abnormalities (perhaps similar to alopecia X in the Nordic breeds and miniature poodle) include alopecia of the Irish water spaniel, Chesapeake Bay retriever and Portuguese water dog. They often have abnormalities in sex hormone panels and histopathologic changes that suggest follicular dysplasia (clumped pigment in hair follicle and/or hair shaft). Although melatonin has not been reported to be effective in treating these individuals, the author has had some success with this drug in treating Chesapeake Bay retrievers with this problem.

OTHERS

Canine Pattern Alopecia (Pattern Baldness)

Signs include symmetrical hair loss behind the ears, ventral cervical, chest and abdomen, caudal thighs and perianally. It is seen primarily in the Dachshund, Boston Terrier, Chihuahua, Whippet, Italian Greyhound, greyhound, Boxer, and miniature pinschers. Individuals begin to lose hair about 6 months of age and gradually progress. Diagnosis by biopsy (follicles are both shorter and thinner than normal and residual hair shafts are extremely fine). Melatonin has been shown to be effective in regrowing hair in 50% to 70% of cases (1.5–6 mg/dog given BID or TID). Therapy is again used until good regrowth, then discontinued and reinstituted with recurrence of the problem.

Sebaceous Adenitis

An inflammatory destruction of the sebaceous glands accompanied by a defect in epidermal keratiniztion, the keratinization defect is seen as marked superficial and follicular hyperkeratosis. The cause is unknown. Studies done with the standard poodle suggest an autosomal recessive mode of inheritance in this breed.

A "focal form" of this disease is most commonly seen in the Visla and occasionally in other short-coated breeds. Affected dogs are presented with focal areas of alopecia and scaling. The skin is variably erythyematous. The head, back, and sides of the thorax and abdomen are most commonly affected. Diagnosis is by skin biopsy .This manifestation of the disease may, on occasion, be glucocorticoid responsive. Good to excellent responses have bee noted with retinoid therapy (isotretinoin, starting at 1–2 mg/kg/day) or oral cyclosporine therapy (5 mg/kg/day). Once complete remission has been achieved, some dogs will be able to have retinoid or cyclosporine therapy discontinued and will go in to indefinite remission. Others will require daily or every other day maintenance therapy to maintain remission. Topical therapy as outlined below for the generalized form of the disease may be tried, but it is usually not very effective.

The so called "generalized form" of the disease is most common and tends to affect longer haired breeds including the Standard Poodle, Samoyed and Akita and many other breeds (Old English Sheepdog, Toy Poodle, Lhasa Apso, Boxer, Chow Chow, German Shepherd dog and crosses, to mention just a few). Age of onset is usually 1 to 3 years, but the disease may develop in any aged individual. Hair loss is often focal and asymmetrical initially with progression to more symmetrical, generalized hair loss, and scaling. Primary areas of involvement include the head (including face), neck, back, sides of the thorax and abdomen, and anterior aspect of the extremities. The ventrum is usually less affected. Scale is heavy and adhered to the base of the hairs ("follicular casting"). The medial aspect of the pinna and canals are dry and scaly; there is often mild to moderate inflammation in the canals. Affected individuals may be prone to secondary staphylococcal pyoderma. Sebaceous adenitis is usually nonpruritic. The development of pruritus is usually attributed to the presence of secondary pyoderma or concurrent allergic disease.

Diagnosis is based on skin biopsy: there is usually moderate acanthosis and generally severe hyperkeratosis with follicular plugging. There is usually perifollicular inflammation localized in the region of the sebaceous glands. The severity of the inflammation varies from scant to severe (scant in chronic lesions). Sebaceous glands are absent.

There are several options for the treatment of this disease. With topical therapy, the overall goal is to remove scale. Following this there will usually be some hair regrowth, although the coat in general will usually not return to its original fullness. Systemic therapy, specifically with oral cyclosporine, has been noted to be associated with the return to most normal coats.

Option 1: Alpha Keri Bath Oil (or generic) is diluted 50:50 in water and applied over the entire coat/skin. It is left on for 1 to 3 hours, then removed with repeated shampooing (use a mild shampoo such as Ivory dishwater liquid; last shampoo or two can be with a veterinary sulfur/salicylic antiseborrheic shampoo). Repeat every 3 to 4 weeks until the scale is gone, then reduce frequency to maintenance. If not too labor intensive for the owners, ideally bathe with an anti seborrheic shampoo once weekly between oil baths. Ideally follow each of these antiseborrheic baths with a good conditioner (eg, Resi conditioner such as ResiSoothe; Allerderm/Virbac). Between more intensive oil therapies, propylene glycol (eg, Humilac) or propylene glycol (PG) diluted 50:50 with water can be sprayed on to the skin and left on once every day or other day. Some use this PG regimen instead of the more intense oil therapy: PG sprays daily; shampoo with antiseborrheic shampoo every 3 to 7 days initially; once scale is gone, start to decrease frequency of bathings first, then topical sprays. Long-term maintenance goal - Bath every 2 weeks, PG sprays 2 times per week. If desired, can use more concentrated propylene glycol spray. To reduce the need for more aggressive topical therapy patients are also treated with oral Vitamin A, 8,000 to 20,000 IU BID (50% show at least partial improvement) and fatty acids (Derm Caps (DVM) ES, 1 capsule BID; Evening Primrose oil, 500 mg BID).

Option 2: Oral tetracycline/niacinamide (500 mg of each/dog TID to initiate therapy) or tetracycline alone +/- topical therapies noted above.

Option 3: Cyclosprine (5 mg/kg q 24 hours orally) has been reported effective in dogs. Following the attainment of maximal response, the frequency or dose of cyclosporine is reduced. Topical cyclosporine (as a 1:10 dilution in water; used as a spray once daily to initiate therapy) has also been used effectively. Of all the therapies for sebaceous adenitis, cyclosporine appears to result in hair regrowth that is closest to normal. This therapy is also noted to potentially result in the regrowth of sebaceous glands.

GERIATRÍA ¿PREVENIMOS O CURAMOS?

Fernando J. Alvarez, DVM
Ex Docente de la Universidad de Bs.As
Práctica Privada en Animales de Compañia
Buenos Aires, Argemtina

La población geriátrica tanto de seres humanos como de perros y gatos se ha incrementado en los últimos años, debido al avance de la ciencia y a una alimentación más racional que permiten una mayor sobrevida.

Debemos tener en cuenta que casi el 40% de la población canina y felina que el médico veterinario atiende en su consultorio se encuentra en edad geriátrica.

Hay diversas hipótesis sobre que causa el envejecimiento y si bien ninguna lo explica por sí misma, la que ha tomado más importancia en los últimos tiempos es la acumulación en el organismo de residuos metabólicos como los radicales libres, responsables de la oxidación y destrucción de las membranas celulares.

Debido a esto último, la prevención, retardo o tratamiento de los síntomas de envejecimiento no pueden hacerse en base a una sola medicación.

Cuando el médico clínico se encuentra frente a un paciente geriátrico se encuentra con una multiplicidad de problemas que debe tener en cuenta, puede que el cuadro predominante sea osteoarticular, ocular, dérmico, renal, etc., o lo más común que sea una mezcla de todas esas patologías. Frente a este panorama tenemos dos alternativas, tratamos al paciente con la vista puesta en la enfermedad predominante o lo vemos como una integridad y le suministramos un tratamiento que apunte a mejorar al animal integralmente.

Sabemos que los animales domésticos envejecen de manera diferente de acuerdo a tamaño, peso y raza del animal.

Los animales de mayor tamaño envejecen con más rapidez que los más pequeños, los más gordos que los más delgados y los de raza más rápido que los mestizos.

A modo de ejemplo la siguiente tabla nos muestra los años promedio de vida en razas grandes comparada con las de menor peso y tamaño.

Debemos tener en cuenta que en la vida de una mascota hay dos momentos en que el propietario le presta mayor atención, la primera es cuando lo compra, es decir, de cachorro y el segundo momento es cuando envejece y el vínculo con el animal se hace más fuerte.

Cuando es cachorro los clínicos implementamos un plan de prevención que emplea vacunas, desparasitaciones y medidas higiénicas de todo tipo para evitar la enfermedad.

El propósito de esta presentación es que tratemos de hacer lo mismo en el otro extremo de la vida del animal.

Como se dice al principio la teoría que mayor importancia ha tomado en la explicación del envejecimiento es la acumulación de radicales libres. Los mismos actúan en diferentes lugares de la célula, como los fosfolípidos de las membranas o en las mitocondrias y cuando el equilibrio entre radicales libres y mecanismos antioxidantes se vuelca a favor de los primeros se produce el estrés oxidativo y la posterior muerte celular.

Veamos como ocurre este proceso. El organismo posee sistemas enzimáticos endógenos para la prevención del mismo que funcionan desde el comienzo de la vida, ellos son la superóxido dismutasa (SOD), la glutatión peroxidasa (GSH-Px) y la catalasa (CAT), los mismos se ponen en marcha ante la acumulación de

Estimación de la edad media de perros y gatos Geriátricos

Perros de razas pequeñas (0-10 kg) = 11,4 años +/- 1,8 años

Perros de razas medianas (10-25 kg) = 10.9 +/- 1,5 años

Perros de razas grandes (25-45 kg) = 8,8 +/- 1,3 años

Perros de razas gigantes (>45 kg) = 7,4 +/- 1,9 años

Gatos = 11,8+/- 1,9 años

Goldston - 1989

radicales libres y necesitan para un correcto trabajo la presencia de elementos como el cobre, zinc y manganeso en el caso de la superóxido dismutasa y de selenio en el caso de la glutatión peróxidasa.

Pero eso no alcanza, el organismo para mantener un equilibrio favorable, requiere la incorporación de antioxidantes con la dieta, ejemplo de ellos son las vitaminas E y C, la taurina y los carotenoides.

Cuando estos mecanismos tanto endógenos como exógenos se resienten el predominio de los radicales libres lleva al estrés oxidativo al actuar sobre el ADN celular, produciendo , alteración en la expresión del gen, destrucción de los mecanismos de reparación tisular y distorsión de la función celular.

Todo esto ocasiona la muerte celular, que a su vez produce la aparición de enfermedades relacionadas con el envejecimiento, así tendremos un organismo con enfermedad cardiovascular, respuesta inmunitaria baja, disfunción cognoscitiva y tantas otras patologías.

Ya se dijo que al tratar un geronte estamos tratando varias patologías simultáneamente. ¿Qué hacer entonces?

El clínico debe implementar un plan para cuidar mejor al animal añoso.

Debemos tener en cuenta que un animal a partir de los siete u ocho años requiere cuidados especiales, por lo tanto la atención en consultorio deberá poner en práctica entre otras cosas análisis clínicos, mayor frecuencia de visitas y educación al propietario sobre los síntomas a tener en cuenta.

Los propietarios en general aceptan las sugerencias del médico veterinario, pues debemos tener en cuenta que en muchos casos al animal se lo atiende desde su nacimiento. Si logramos que el dueño de la mascota entienda la importancia de un plan de prevención de la vejez, evitaremos tener que atender pacientes que llegan al consultorio en un estadío final y con pocas posibilidades de solución. Por otra parte habremos logrado fortalecer la relación médico veterinario – dueño de la mascota y obtener un beneficio compartido, pues al propio beneficio económico que esto conlleva, se debe sumar el beneficio de satisfacción del propietario y lo más importante retrasar los síntomas de envejecimiento y mejorar la calidad de vida de nuestro paciente en esta etapa.

¿EL ENVEJECIMIENTO, SE PUEDE DIAGNOSTICAR?

Fernando J. Alvarez, DVM
Ex Docente de la Universidad de Bs.As
Práctica Privada en Animales de Compañia
Buenos Aires, Argemtina

El envejecimiento es un proceso gradual, progresivo y al mismo tiempo irreversible, por lo tanto, la teoría de la juventud eterna por el momento debemos descartarla.

De todas formas en este camino hacia la senilidad no siempre la edad biológica es coincidente con la cronológica, es decir que un animal de doce años que cronológicamente es un animal senil puede biológicamente estar mejor que uno de ocho años.

Está probado que los animales envejecen de diferente forma de acuerdo al tamaño, peso, raza, etc. Los animales de mayor porte como un Gran Danés, comienzan su proceso de envejecimiento entre los seis y siete años mientras que un Yorkshire Terrier es probable que presente síntomas seniles recién a los diez u once años.

A estas diferencias raciales y genéticas tienen que sumarse otras, como diferentes condiciones ambientales, tipo de alimentación, cuidados a lo largo de la vida, que hacen que un animal pueda deteriorarse más rápido que otro.

El envejecimiento lleva como consecuencia final a la muerte del animal, en aquellos que mueren tempranamente la misma en general está asociada con alguna enfermedad subyacente grave.

Entonces, como conclusión, podemos decir que los cambios del envejecimiento son progresivos e irreversibles y tienen que ver con una combinación de factores como las enfermedades, el estrés, la nutrición, los factores genéticos, el medio ambiente y el ejercicio.

A pesar de ello no podemos afirmar que la vejez es sinónimo de mala salud, en algunos animales esto se puede dar simultáneamente pero no siempre es así.

Dice el Doctor Johnny D. Hoskins en su libro sobre Geriatría y Gerontología del perro y el gato “la prevención, la detección temprana y la intervención oportuna en los problemas médicos pueden ejercer un impacto significativo sobre la supervivencia y la calidad de vida de un perro o gato de edad avanzada”.

Los clínicos veterinarios deben tener en cuenta qué hacer con el propietario de una mascota que llega a los siete u ocho años de edad. Esta es una tarea docente basada en enseñarle al dueño básicamente dos cosas, la primera estar atento a síntomas clínicos que son fáciles de ver y que en general pasan desapercibidos o no se les da importancia.

El segundo punto sobre el que debemos instruir al dueño de la mascota senil es en la necesidad de controles periódicos para poder adelantar nuestro diagnóstico y así utilizar los recursos terapéuticos necesarios para demorar todo lo posible los síntomas clínicos de enfermedad.

Para comenzar podríamos hacer un listado que debería comprender entre otros los siguientes:

- Problemas locomotores simples como dificultad en subirse a un sillón, cama, al auto, etc.
- Aumento en la ingesta de líquido y emisión de orina (polidipsia y poliuria)
- Trastornos en la visión.
- Olor en la piel.
- Aumento en la caída de pelo
- Cambios de hábitos higiénicos, sobre todo en los felinos que viven en departamentos y tienen lugares fijos para sus deposiciones y micciones.
- Cambios de conducta, ya sea, que estos viren a la agresividad o pasividad del animal.
- Dificultad en adaptarse a situaciones nuevas y al reconocimiento de personas con las cuales ha convivido el animal durante años.

Este listado que podría comprender varios puntos más, debería ser provisto al propietario de una mascota para que nos ayude en el diagnóstico precoz del envejecimiento. La rapidez en la detección de estos síntomas, que muchos entenderán como síntomas subjetivos, y es cierto que lo son, nos permitirán adelantarnos a síntomas más objetivos pero también más graves.

El veterinario clínico no debe esperar a tener frente a él un animal con parálisis o paresia del tren posterior, o con una insuficiencia renal para comenzar un tratamiento.

Así como en el cachorro implementa un plan de vacunación, desparasita y toma los recaudos para realizar un plan sanitario que permita al animal crecer y desarrollarse sin enfermedades; en el otro extremo de la vida, que es la vejez, debe buscar recursos para adelantarse a la aparición de síntomas. De esa manera, no evitará la presentación de enfermedades graves que seguramente llegarán, sino logrará retrasar la aparición de sus síntomas y dará mejor calidad de vida a la mascota en tratamiento.

Además de estos síntomas subjetivos que pueden ser motivo de discusión hay otros que podemos objetivar.

El tercer punto sobre el que se debe instruir al dueño de la mascota senil es la necesidad de controles periódicos para poder adelantar el diagnóstico y poner en práctica los recursos terapéuticos necesarios para demorar todo lo posible síntomas graves de enfermedad.

Hay trabajos realizados donde se observó y analizó la correlación entre parámetros sanguíneos y la edad y donde se concluye, que con el paso de los años, algunos de ellos aumentan y otros disminuyen.

Entre los valores que tienden a aumentar se encuentran los siguientes: urea, fósforo inorgánico, glucosa, potasio, volumen corpuscular medio, leucocitos totales, neutrófilos y eosinófilos. Los que disminuyen son: calcio, linfocitos y eritrograma.

El clínico veterinario tiene a su disposición valores hemáticos de referencia para animales jóvenes y adultos, pero carece todavía de suficientes estudios poblacionales para estandarizar "valores fisiológicos" en el animal geronte.

De todas formas es real que un aumento por encima de los valores fisiológicos en un animal de más de siete u ocho años está señalando que algo pasa. Para poner un ejemplo que se entienda: si llega un paciente de esta edad con una uremia de 50 o 60 mg/dl, no se puede asegurar que el animal tenga una insuficiencia renal, pero se debe pensar que ese riñón seguramente tiene un daño en un número importante de nefrones que seguramente disminuye la filtración glomerular. Lo mismo estará pasando en otros órganos que van lentamente deteriorando sus funciones y modificando gradualmente los valores sanguíneos.

Es aquí donde cobra importancia la implementación de controles periódicos al gerente, dentro de un plan integral de salud que permita al clínico realizar un diagnóstico precoz y no esperar a tener uremias de 300 o 400 mg/dl frente a las cuales probablemente sea poco lo que se puede hacer.

La puesta en práctica de este tipo de controles que podemos llamar "perfil geriátrico", busca tener un diagnóstico de envejecimiento y al mismo tiempo parámetros cuantificables y así poder seguir la evolución del proceso y la respuesta al tratamiento establecido.

Si se comienza a implementar este método seguramente se logrará retrasar la aparición de síntomas más graves y mejorar la calidad de vida del animal geronte.

ENFERMEDADES OSTEOARTICULARES: UN PROBLEMA DEL GERONTE

Fernando J. Alvarez, DVM
Ex Docente de la Universidad de Bs.As
Práctica Privada en Animales de Compañia
Buenos Aires, Argemtina

El incremento que ha sufrido el promedio de vida de nuestras mascotas, debido a una mejor atención médica, una mejor alimentación y un mayor contacto con el ser humano aumentó el porcentaje de animales gerontes que el médico veterinario diariamente debe atender en su consultorio.

Dentro de las patologías más comunes que pueden observarse están, sin ninguna duda, las enfermedades músculoesqueléticas. Estas se pueden presentar como enfermedad única o en combinación con patologías renales, cardíacas, etc.

Sin duda, la enfermedad músculoesquelética por excelencia es la enfermedad articular degenerativa. Se caracteriza por un cambio degenerativo en el cartílago articular y tiene, una forma primaria, cuando lo que produce ese cambio es sólo el envejecimiento, o una forma secundaria, que aparece cuando hay una enfermedad previa, como la displasia de cadera o una osteocondritis disecante ó una causa traumática como la ruptura de ligamentos cruzados.

Es importante cuando se encara el diagnóstico de esta enfermedad tratar de ver al paciente como una integridad y no sólo como una rodilla o cualquier otra articulación enferma.

Las enfermedades osteoarticulares requieren un tratamiento que considere no sólo la patología puntual sino una visión general del paciente. Para dar un ejemplo: si vamos a tratar una enfermedad articular degenerativa primaria en un perro obeso, lo primero que debemos hacer es ponerlo a dieta y que baje de peso, de lo contrario los tratamientos a implementar tendrán destino de fracaso.

Con el correr de los años hay cambios degenerativos en el cartílago articular, los cuales modifican la histología y la bioquímica articular.

Veamos los constituyentes normales de una articulación y como se produce el deterioro que lleva a la enfermedad, para después poder instaurar el mejor tratamiento posible.

Articulación: Componentes

- Hueso Subcondral
- Cartílago
    - Células: Condrocito
    - Matriz extracelular: Fibras Sustancia básica (mucopolisacáridos)
- Membrana sinovial
- Cápsula articular–Ligamentos intra y extrarticulares
- Líquido sinovial

Siguiendo el cuadro debemos considerar en primer lugar al hueso subcondral que da soporte a la articulación, siendo el último receptor de las presiones articulares. Tiene una estructura esponjosa que protege al cartílago del daño traumático. El endurecimiento del hueso subcondral que ocurre en la artritis puede llevar a la muerte del cartílago, está muy inervado e irrigado.

El cartílago articular normal es denso, blanco y brillante, con el tiempo adquiere una coloración amarillenta. La superficie del mismo no es plana, tiene pequeñas depresiones irregulares correspondientes a la localización de los condorcitos por debajo de la superficie articular. Carece de inervación e irrigación y su composición es básicamente un 70% de agua y un 30% de colágeno y proteoglicanos.

El condrocito es el único elemento vivo del cartílago y por lo tanto, es el único que elabora los componentes del mismo, de allí la importancia de mantener el equilibrio entre el anabolismo y catabolismo del mismo, para asegurar el normal funcionamiento del cartílago.

El condrocito produce fibras colágenas, elásticas y mucopoliscáridos,entre estos últimos encontramos a los proteoglicanos y al ácido hialurónico. Los proteoglicanos forman la base de sustentación de los GAGS, dan soporte a las células, resisten la compresión y forman filtros moleculares, retrasando el movimiento de microorganismos y células metastásicas. El ácido hialurónico producido por el condrocito, se une con los proteoglicanos formando una macromolécula de mucopolisacáridos, de esta manera,
participa dando resistencia a la compresión del cartílago.

En resumen el cartílago articular no tiene inervación , ni irrigación y se nutre por difusión a partir de los vasos sanguíneos de la membrana sinovial. La difusión se realiza a través del agua.

La membrana sinovial contribuye a la estabilidad articular, produce líquido sinovial y transporta nutrientes hacia la articulación y residuos metabólicos fuera de la misma .

En cuanto a la cápsula articular incluye una cantidad significativa de tejido que permite un amplio movimiento articular, pero a la vez actúa como estabilizador de la articulación, en particular si es tensionada en los extremos de flexión o extensión.

Por último, el líquido sinovial es un dializado sanguíneo originado en los plexos de la capa de sostén de la membrana sinovial. Es un líquido viscoso, transparente e incoloro. Las articulaciones normales contienen sólo un volumen reducido del mismo. Podemos decir que el líquido sinovial es plasma más ácido hialurónico y que actúa en la lubricación de tejidos blandos y del cartílago articular, evitando la migración leucocitaria y disminuyendo la síntesis de PGE_3.

¿Cómo llegamos a la enfermedad? La enfermedad osteoarticular se define como la pérdida del cartílago articular y muerte de los condrocitos.

Para ser más específicos digamos que la enfermedad articular degenerativa es una enfermedad progresiva compleja que puede definirse de varios modos. En términos patológicos "es un desorden intrínsecamente no inflamatorio de las articulaciones móviles (sinoviales) caracterizado por el deterioro del cartílago articular y la neoformación ósea en las superficies y márgenes articulares".

Desde el punto de vista clínico es "una enfermedad articular de evolución lenta caracterizada por el desarrollo gradual de dolor, rigidez y restricción del movimiento articular".

Esta enfermedad tiene una etiología multifactorial donde intervienen factores genéticos, metabólicos, biomecánicos, etc.

La causa última en su aparición se debe al desequilibrio entre el desgaste permanente al que está sometido el cartílago articular, frente a la limitada capacidad regeneradora de este tejido.

La fisiopatología nos muestra una disminución del anabolismo, pues el condorcito disminuye la producción de proteoglicanos, colágeno tipo II, agua y ácido hialurónico y al mismo tiempo hay un aumento del catabolismo representado por la presencia de enzimas proteolíticas como las colagenasas que terminan produciendo la muerte del condrocito.

Esto afecta también a la membrana y al líquido sinovial, en la primera se inicia el proceso inflamatorio y el segundo cambia su composición y apariencia, disminuída entonces la capacidad de amortiguación, se fisura el cartílago articular y aparece el dolor. También el hueso subcondral comienza a sufrir impactos, se esclerosa, se producen micro fracturas y todo esto lleva a la formación de osteofitos.

Frente a este cuadro el objetivo del tratamiento será recuperar la función articular, tratando de inhibir la inflamación, aliviar el dolor, regenerar las superficies articulares, recuperar el cartílago y reparar el hueso subcondral.

El tratamiento puede ser encarado con antiinflamatorios no esteroides (AINES), antiinflamatorios esteroides, condroprotectores o regeneradores osteoarticulares o en algunos casos una combinación de ellos.

Pero lo más importante en este caso es tener en cuenta al paciente como una integridad, tener en cuenta que estamos frente a un paciente geronte que seguramente además de la patología articular, tiene daños en otros órganos del cuerpo, que este tratamiento se prolonga en el tiempo y que lo que debemos hacer es causar el menor daño posible, tratando de minimizar los efectos colaterales del mismo.

De los tratamientos antes mencionados los que reúnen estas condiciones, o sea, poder ser utilizados por largo tiempo y con el menor efecto colateral, están los condroprotectores como la glucosamina y el condroitín sulfato y los regeneradores articulares que agregan a los anteriores, aminoácidos, minerales como el cobre, zinc, magnesio y manganeso, vitaminas como la E y el grupo B que permiten un tratamiento sin complicaciones secundarias.

Es importante complementar estos tratamientos con otras medidas terapéuticas como la fisioterapia y la rehabilitación y la instrucción al propietario en el manejo del animal, indicando en caso de ser necesario, dietas, ejercicios moderados, aplicación de calor seco en las zonas afectadas o cualquier otra medida que ayude a la recuperación fisiológica del paciente.

DIAGNÓSTICO DE DISFUNCIÓN COGNOSCITIVA

Fernando J. Alvarez, DVM
Ex Docente de la Universidad de Bs.As
Práctica Privada en Animales de Compañia
Buenos Aires, Argemtina

Entre las enfermedades comunes del animal geronte se encuentran distintas manifestaciones de la conducta que en muchas oportunidades no son advertidas por el propietario y que deben figurar como síntomas de alerta en los planes de atención geriátrica de los diferentes centros hospitalarios.

El proceso de envejecimiento es lento e irreversible y en él se manifiesta un deterioro de la función cognoscitiva como la pérdida de memoria, la falta de percepción, el olvido de las conductas aprendidas y también de la conciencia.

Estos cuatro enunciados generales tienen un correlato con síntomas concretos que observa el propietario y el clínico en la práctica diaria.

Los animales con deterioro cognoscitivo no se ubican en tiempo y espacio, aún dentro de su propio hogar, pueden desconocer a quienes viven con ellos, volverse agresivos con las personas o con otros animales, pierden los hábitos aprendidos, como los de higiene y pueden comenzar a evacuar dentro del hogar.

Son muchos los síntomas que pueden poner de manifiesto el deterioro cognoscitivo y es muy importante que el clínico pueda diferenciar éstos, de una manifestación de enfermedad.

Para ello es importante realizar pruebas de laboratorio que nos permitan descartar la enfermedad; hemograma y perfil bioquímico, hepatograma, análisis de orina, radiografía, ecografía, electro o ecocardiograma o cualquier otra prueba que el médico veterinario necesite para el diagnóstico diferencial, debe ser usada.

Una vez descartada la causa orgánica, debemos analizar que ocurre en el ambiente. En muchas oportunidades la llegada de un bebé al hogar, un divorcio, la presencia de otra mascota, etc., pueden alterar la conducta del animal sin que esto sea un síntoma de disfunción cognoscitiva.

Como se ve no es fácil llegar a un diagnóstico certero y en ese sentido debemos tener en cuenta que el animal geronte difícilmente presente un solo problema. Lo más común es que sea una combinación de patologías.

Es probable que un perro de diez años con cataratas, tenga además de la dificultad visual, una artrosis y si es un macho, algún problema prostático. Entonces será difícil de evaluar, cuando el animal se torna agresivo al acercarnos, si lo hace porque tiene dolor por la artrosis, si no nos reconoce porque no nos ve o si esto es causa del deterioro cerebral por la edad.

Como otro ejemplo de lo dicho, los problemas osteoarticulares provocan dolor, disminución de la masa muscular y dificultad en el movimiento, estos procesos son crónicos, por lo tanto, el malestar que siente el animal también lo será y probablemente el dolor y la falta de movilidad hagan que el animal no pueda llegar a los sitios de evacuación habituales.

Es muy importante por lo tanto, poder diferenciar los cambios de conducta secundarios a distintas patologías, de los cambios de conducta producto del deterioro cerebral.

Debemos tener presente que los cambios degenerativos cerebrales tienen como consecuencia la disfunción cognoscitiva.

En un geronte se produce un achicamiento de la masa cerebral, hay reducción del número de neuronas, desmielinización y degeneración neuroaxonal. También cambios vasculares y perivasculares que incluyen la hemorragia y los infartos.

Cada día hay más pruebas sobre la responsabilidad que la acumulación del amiloide beta tiene en el desarrollo de la disfunción cognoscitiva, el mismo no se halla en perros jóvenes, pero sí en perros de edad y a mayor acumulación de amiloide, hay un mayor deterioro cognoscitivo.

La acumulación de amiloide beta, trae alteraciones funcionales en los neurotrasmisores, arterioesclerosis no lipídica, placas del mismo en cerebro e hipocampo, insuficiencia vascular, declinación de la actividad colinérgica y mayor producción de radicales libres.

El resultado de esta acumulación y la zona afectada por la misma, será el corolario para la presentación de síntomas clínicos que nos permitirán hacer el diagnóstico de disfunción cognoscitiva.

Finalmente, se presenta una tabla orientativa con los síntomas más comunes de la disfunción cognoscitiva en perros y gatos.

Perros	**Gatos**
Ansiedad por separación	Eliminación en lugares inapropiados
Agresión a personas	Agresión hacia animales de la misma especie
Agresión a animales	Agresión a personas
Trastornos compulsivos	Vocalización excesiva
Fobias	Deambulación nocturna
Ansiedad	Acicalamiento excesivo
Evacuación en el hogar	Miedo
Aumento de vocalización	Arañazos

TRATAMIENTO DE DISFUNCIÓN COGNOSCITIVA

Fernando J. Alvarez, DVM
Ex Docente de la Universidad de Bs.As
Práctica Privada en Animales de Compañia
Buenos Aires, Argemtina

Definimos a la disfunción cognoscitiva como los problemas de conducta causados por los efectos de procesos neurodegenerativos cerebrales.

Siguiendo la definición podemos afirmar que no todos los animales que envejecen sufren disfunción cognoscitiva Esto quiere decir que no es una consecuencia inevitable del envejecimiento y por lo tanto debemos tener la certeza del diagnóstico para poder implementar el tratamiento.

Los cambios que se producen en un cerebro senil abarcan varios aspectos, hay una actividad incrementada de la monoaminooxidasa B (MAOB), disminución en la función de los neurotrasmisores como la noradrenalina, serotonina y dopamina, declinación de la actividad colinérgica y un incremento en la producción de radicales libres.

Otro factor que puede influir, es la insuficiencia vascular, la que podría potenciar el proceso neurodegenerativo al producir hipoxia cerebral.

La falta de oxígeno actúa a nivel de la mitocondria y a medida que ésta envejece produce una mayor cantidad de radicales libres, en caso que la producción de los mismos sea mayor que la capacidad del organismo para poner en acción sus defensas antioxidantes, se produce un proceso llamado estrés oxidativo que termina en la muerte celular.

El cerebro sufre especialmente los efectos adversos que trae la acumulación de radicales libres ya que es un tejido con alta demanda de oxígeno, alto contenido en lípidos y tiene dificultad para poner en marcha los mecanismos antioxidantes y de reparación de sus tejidos.

El tratamiento de la disfunción cognoscitiva debe entonces contemplar dos aspectos, debe hacerse un tratamiento que podemos llamar higiénico o nutricional y otro medicamentoso.

El primero de ellos tiende a aportar al animal un ambiente favorable y cuidados especiales, como ejercicios programados, paseos y otras actividades que mantengan atento al animal.

Además, se debe proveer una dieta rica en antioxidantes que permita contrarrestar el efecto que produce la acumulación de radicales libres.

Es importante suministrar vitamina E y C, ya que la primera protege a las membranas celulares depurando los radicales libres e interrumpiendo la peroxidación de los lípidos y la segunda tiene un papel muy importante como antioxidante, y además ayuda a regenerar a la vitamina E.

También debemos incorporar omega 3 que tiene efectos beneficiosos sobre la circulación sanguínea (microcirculación) fluidificando la sangre al evitar la formación de trombos, asimismo actúa como antioxidante y favorece la formación de mielina.

Por último no deben faltar en la dieta carotenoides y l-carnitina, ya que esta última actúa mejorando la función mitocondrial.

En cuanto al tratamiento médico, el de elección es con selegilina. El clorhidrato de selegilina habitualmente denominado l-deprenil, está indicado en la disfunción cognoscitiva y en el tratamiento del síndrome de Cushing, aunque en este último caso, su uso es controvertido.

En el humano se usa como tratamiento adyuvante de la enfermedad de Parkinson.

La selegilina actúa inhibiendo la monoaminooxidasa, esto produce un aumento en los receptores de dopamina y de otras catecolaminas en la corteza e hipocampo.

También contribuye a disminuir la carga de radicales libres, pues al inhibir a la monoaminooxidasa depura en forma directa a los radicales libres y aumenta el nivel de enzimas depuradoras como catalasa y superóxido dismutasa.

Entre los efectos adversos se incluyen el vómito, la diarrea y efectos nerviosos centrales, como inquietud, movimientos repetitivos o letargia, salivación y anorexia.

De todas formas la experiencia clínica con esta droga es limitada y podría modificarse el perfil de estos efectos colaterales.

La dosis indicada es de 0,5 a 1 miligramo por vía oral, una vez al día, de preferencia por la mañana. Los ajustes de esta dosis se harán de acuerdo a respuesta y tolerancia a la droga.

Entre otros tratamientos que pueden ser utilizados están los siguientes:

- La nicergolina, que es un antagonista α_1 y α_2 – adrenérgico, la dosis recomendada es de 0,25 a 0,5 miligramos/ kilo/ día.
- El clorhidrato de nilidrina, un agonista β – adrenérgico, es un vasodilatador y se dosifica de 3 a 6 miligramos, tres veces al día/ total.
- Por último la propentofilina, aumenta el suministro de oxígeno al sistema nervioso central y se recomiendo una dosis de 3 miligramos/ kilo/ cada 8 horas.

Es importante recordar que el éxito de un tratamiento dependerá no sólo de la utilización de la droga adecuada sino también de la implementación de una nutrición y régimen de actividad acorde a la patología a tratar.

COMO SÉ SI MI PACIENTE TIENE CÁNCER?

C. Guillermo Couto, DVM, Diplomate ACVIM
College of Veterinary Medicine
The Ohio State University, Columbus, OH

Los siguientes signos clícios frecuentemente esan asociados co un diagnóstico de cancer: presencia de un bulto o masa, pérdida de peso, vómitos/diarrea, poliuria/polidipsia (eg; hipercalcemia), hemorragias de orificios naturals, etc. Sin embargo, también pueden deberse a una gran variedad de problemas medicos o quirúrgicos no neoplásicos.

Después de obtener una Buena anamnesis y hacer una exploración clínica, habitualmente el clínico identifica una masa o lesión inflitrativa en este paciente. Cómo determinamos si es una lesion neoplásica o no? El primer paso: CITOLOGIA.

Los especimenes para evaluación citológica son fáciles de obtener. Además, la obtención de la muestra habitualmente no requiere anestesia local o general, los resultados son rápidos, y el porcentaje de complicaciones es extremadamente bajo.

La mayoría de los tejidos pueden ser evaluados a través de citología, incluyendo lesiones de piel, ganglios linfáticos superficiales y profundos, órganos parenquimatosos, lesiones pulmonares intersticiales o metastáticas, y efusiones en cavidades corporales. En general, para hacer una punción se utiliza una aguja fina (calibre 22, 23, ó 25 G), ya que una aguja de diámetro más grande habitualmente obtiene un pequeño "tapón" de tejido, con el cual es muy difícil hacer extendidos.

OBTENCIÓN DE MUESTRAS

Existen varias técnicas para obtener muestras para citología. Una vez que se ha obtenido la muestra, los frotis son procesados en forma similar.

Aspiracion por Aguja Fina (Puncion)

Usando esta técnica, es posible obtener una suspension monocelular a través de una aguja fina (calibre 22, 23, ó 25G) acoplada a una jeringa de 12 a 20 ml (o no). Es muy fácil aspirar masas de piel o tejido subcutáneo, ganglios superficiales o profundos, bazo, hígado, riñones, pulmones, tiroides, próstata, y tumores intracavitarios (eg; masas mediastínicas).

Cuando se punza un tumor superficial o un ganglio, no hace falta preparar el área en forma estéril. Sin embrago, cuando se aspira una masa u órgano intracavitario, es preferible afeitar y esterilizar la zona. Una vez que la masa ha sido identificada a través de palpación, radiografías, o ultrasonido, se la debe "fijar" por medio de la palpación. Inmediatamente se inserta una aguja (acoplada a una jeringa descartable o no) en la masa/órgano afectado; si no se usa jeringa, punzamos la masa varias veces insertando y sacando la aguja. Una vez retirada la aguja de la masa, se pone aire en una jeringa y se expele el contenido en portaobjetos (laminillas) como se decribe más abajo. Si se usa jeringa, se aplica succión con el émbolo 3 ó 4 veces. Se debe interrumpir la succión antes de retirar la aguja de la masa/órgano, ya que de no ser así, las células se van a aspirar dentro de la jeringa, donde no son accesibles. Una vez removidas la aguja y jeringa juntas, se separa la aguja de la jeringa, y una vez aspirado aire dentro de la jeringa, la aguja se vueleve a acoplar, y el material se expele en varios portaobjetos. En la mayoría de los casos, no hay material en la jeringa, ya que la cantidad de células contenidas en la aguja son suficientes para hacer de 4 a 10 frotis. En la clínica hacemos frotis "de tirado" en vez de hacer los frotis hematológicos tradicionales. Una vez hechos los frotis, se secan al aire y se colorean con Diff-Quik, Giemsa, o May-Grunwald.

Liquidos de Puncion

Después de obtener líquidos de punción, es preferible preservar las muestras en tubos con y sin anticoagulante, ya que el alto contenido de fibrinógeno de algunos liquidos hace que coagulen rapidamente. Además de hacer una evaluación bioquímica del líquido, es importante evaluar la muestra citologicamente. Para ello, habitualmente hacemos un frotis directo y un frotis después de haber centrifugado la muestra a baja velocidad (1.500 rpm).

TÉCNICAS DE COLORACIÓN

Las técnicas de coloración que más usamos en la clínica son la Diff-Quik, y las coloraciones hematológicas de Wright, Giemsa, y May-Grunwald.

INTERPRETACIÓN

Procesos Inflamatorios

Las reacciones inflamatorias se caracterizan por la abundancia de células inflamatorias en la lesión. El tipo de célula que predomina depende del agente etiológico que indujo la inflamación (eg; neutrófilos en infecciones piogénicas, eosinófilos en inflamaciones alérgicas o parasitarias) y del curso del proceso inflamatorio (eg; neutrófilos en la mayoría de los procesos agudos y macrófagos y linfocitos en los procesos crónicos).

Agentes Etiologicos

Ciertos agentes etiológicos son fáciles de identificar en preparados citológicos, incluyendo *bacterias, histoplasma, blastomyces, cryptococcus, coccidioides, aspergillus/penicillium, rickettsias, demodex, y toxoplasma.*

Tumores Malignos

La mayoría de las células somaticas, con excepción de los precursores hemáticos en la médula ósea, son bien diferenciadas. Las células neoplásticas tienen una o más de estas características: aumento de la relación nucleo:citoplasma; cromatina fina; nucléolos; amoldamiento nuclear; uniformidad morfológica; pleomorfismo; vacuolización; anisocitosis; y anisocariosis. Además de esto, las células neoplásticas habitualmente difieren morfologicamente de la población progenitora.

Carcinomas vs. Sarcomas vs. Tumores de Celulas Redondas

Carcinomas

La mayoría de los carcinomas continene células redondas o poligonales que forman grupos (interacción célula a célula). Tienen un citoplasma azul oscuro, y en la mayoría de los adenocarcinomas hay vacuolas evidentes. En los carcinomas espinocelulares, las células aparecen como células individuales.

Sarcomas

Las características típicas de los sarcomas incluyen células fusiformes o poligonales que no se asocian con la célula vecina, que tienen citoplasma rojizo a azulado, y núcleos irregulares. Muchas de las células mesenquimáticas tienen projecciones del citoplasma que semejan velos o colas. Es importante recordar que en un porcentaje variable de sarcomas, las células no exfolian bien, por lo tanto una punción puede dar resultados "negativos". En esos casos, es importante hacer una biopsia quirúrgica.

Tumores de Celulas Redondas

Los tumores compuestos de una población monomórfica de células redondas individuales se denominan tumores de células redondas, e incluyen linfomas, tumores venéreos transmisibles, histiocitomas, mastocitomas, plasmacitomas, y melanomas. Las células en los melanomas y mastocitomas contienen gránulos.

COMO TRATO A MI PACIENTE CON CÁNCER?

C. Guillermo Couto, DVM, Diplomate ACVIM
College of Veterinary Medicine
The Ohio State University, Columbus, OH

En las ultimas décadas varias modalidades terapéuticas han sido usadas en perros y gatos con cancer, incluyendo cirugía, radioterapia, quimioterapia, immunoterapia, criocirugía, fototerapia, hipertermia, y tratamientos no convencionales, entre otras. Sin embargo, hasta hace dos o tres décadas, la cirugía constituía el principal método de tratamiento en animales con cáncer. Hoy en día, los tumores no-resectables o metastáticos pueden tratarse con variados grados de éxito usando una o más de estas modalidades.

Las primeras cuatro modalidades de tratamiento se describirán en la sección siguiente. Hiperthermia consiste en aplicar calor (comúnmente 42 C) al tumor o al paciente, usando una variedad de métodos; usada por sí misma, es efectiva en gatos con pequeños carcinomas espinocelulares superficiales, y en combinación con radioterapia es beneficioso en algunos perros y gatos con fibrosarcomas y hemangiopericitomas; sin embargo, practicamente no se utiliza. La criocirugía se basa en congelar las células neoplásticas; la liberación de antígenos tumorales estimula una reacción inmunológica local (y probablemente sistémica). La criocirugía se ha usado exitosamente en perros y gatos con pequeños neoplasmas superficiales (e.g.; carcinomas espinocelulares, basaliomas). En la fototerapia, el paciente recibe una droga fotosensibilizante que es eliminada rápidamente en la mayoría de las células normales, pero que se retiene en forma perinuclear en las células neoplasticas. La exposición del tumor a un rayo de laser causa excitación de las moléculas fotosensibilizantes, resultando en liberación de energía y muerte celular. Sin embargo, esta técnica es efectiva sólo en tumores de menos de 0,8 a 1 cm de diámetro o profundidad. La termoquimioterapia consiste en generar temperaturas altas en y alrededor del tumor, al mismo timepo que se administra quimioterapia por vía local o sistémica; la temperatura local alta resulta en captación diferencial del agente antitumoral en las células neoplásticas.

Cuando se evalúa un gato o un perro con un tumor maligno, el clínico se debe dar cuenta que en la mayoría de casos, dada la opción, los propietarios elegirán tratar sus animales. Aunque la eutanasia todavía representa una alternativa razonable para el "tratamiento" de cáncer en animales pequeños, se debe hacer un esfuerzo para investigar otras opciones de tratamiento.

El tratamiento de cáncer puede ser o paliativo o curativo. De ser posible, se deberían erradicar todas las células tumorales en el paciente (obtener una cura) ni bien hecho el diagnóstico. Esto significa acción inmediata, en vez de "esperar-y-ver-que-ocurre". Con muy pocas excepciones, los tumores malignos no regresan espontáneamente. Por lo tanto, demorar el tratamiento en un paciente en el cual se sospecha (o se ha confirmado) un tumor maligno, habitualmente aumenta la probabilidad de que el tumor se disemine localmente o desarrolle metástasis (y por lo tanto disminuye la probabilidad de curar al paciente). La cirugía, la radioterapia, y la hipertermia son tratamientos potencialmente curativos; mientras que la quimioterapia y la inmunoterapia son comúnmente paliativas (ver más adelante).

Como discutimos en el párrafo previo, una vez establecido un diagnóstico de cáncer, la primera decisión que debe hacer el clínico es si el tumor es potencialmente curable. De ser así, se debe hacer un esfuerzo lo antes posible para tratar de eliminar completamente todas las células tumorales. La mayoría de los pacientes con tumores locales (sin metástasis) y algunos pacientes con tumores regionales pueden curarse usando el tratamiento apropiado (cirugía agresiva, radioterapia, o combinaciones de ambos). Ejemplos de estos tumores incluyen, entre otros, fibrosarcomas en perros y gatos, hemangiopericitomas en perros, carcinomas de mama de menos de 2 cm de diametro, y carcinomas espinocelulares de cabeza y cuello en gatos.

Si un paciente tiene un tumor diseminado (linfoma) o un tumor metastático (osteosarcoma, hemangiosarcoma), la probabilidad de lograr una cura es extremadamente baja (< 10%). Sin embargo, en la mayoría de estos pacientes, los tratamientos paliativos resultan en remisiones prolongadas (12 a 18 meses en perros con linfoma ú osteosarcoma tratados con quimioterapia, o cirugía/ quimioterapia, respectivamente). Ciertos tumores, como los tumores venéreos trasmisibles, habitualmente se curan con quimioterapia (vincristina).

Si el clínico juzga que el paciente no puede ser curado, debe tomar la decisión de usar tratamiento paliativo o no. En este momento, es apropiado discutir la eutanasia (como una alternativa potencial) con el propietario.

Dependiendo del tipo de tumor, su comportamiento biológico, y su "staging", se pueden recomendar una o más de las opciones que hemos discutido. Sin embargo, se debe recordar que además de los factores relacionados al tumor (tipo histopatólogico y grado de diferenciación, "staging" o grado de diseminación, la respuesta a tratamientos específicos), hay una multitud de factores que influyen la selección del tratamiento óptimo.

Es importante recordar que el mejor tratamiento para un tipo particular de tumor no constituye necesariamente el mejor tratamiento para un propietario o paciente en particular. El factor más importante a considerar en el paciente es su actividad y salud general (o escala de perfomance)(Tabla). Por ejemplo, un gato o perro con actividad notablemente disminuida y signos constitucionales severos (pobre escala de perfomance) no constituye un candidato bueno para usar quimioterapia agresiva o para las anestesias repetidas que se necesitan para utilizar radioterapia.

En el paciente con un tumor, las dos metas principales de tratamiento paliativo de cáncer son la inducción de remisión y la buena calidad de vida. La remisión se refiere a una disminución en la masa tumoral. Si no se puede mantener una buena calidad de vida, el tratamiento se debe modificar o interrumpir.

Finalmente, la mayoría de los gatos y perros con cáncer se tratan usando un enfoque de equipo. Este equipo incluye el paciente, el propietario, el oncólogo clínico, el cirujano oncológico, el radioterapista, el patólogo clínico, y el patólogo. La interacción entre los miembros del equipo resulta en beneficios marcados para el animal afectado y sus propietarios.

Tabla 1. Escala de perfomance de Karnofsky para perros y gatos.

Grado de Actividad	
0 - Normal	Totalmente activo, actividad similar an antes de enfermarse
1 - Restringido	Actividad restringida en comparación con antes de enfermarse, pero capaz de funcionar como un animal aceptable
2 - Actividad comprometida	Severamente restringida; ambulante únicamente para comer, defecando y orinando en áreas aceptables
3 – Incapacitado	Completamente incapacitado; debe ser alimentado a fuerza; incapaz de restringir orina y defecación a áreas aceptables
4 - Muerto

QUIMIOTERAPIA DE REINDUCCION EN EL PERRO CON LINFOMA

C. Guillermo Couto, DVM, Diplomate ACVIM
College of Veterinary Medicine
The Ohio State University, Columbus, OH

Linfoma (linfosarcoma, LSA) es el tumor hemolinfático más común en el perro. La forma anatómica de presentación más común es la multicéntrica, en la cual linfadenopatía generalizada masiva (ocasionalmente asociada con hepato-esplenomegalia) es el signo cardinal. En algunos pacientes las lesiones extranodales son comunes (piel, sistema nervioso central, riñón). El diagnóstico de linfoma multicentrico es relativamente sencillo, ya que la aspiración por aguja fina revela una población monomórfica de células linfoides neoplásticas. El fenotipo del tumor tiene implicaciones pronósticas; en el perro, los pacientes con linfoma de células B tienen major pronóistico que los de células T.

Como los linfomas son tumores sistémicos, el mejor tratamiento es la quimioterapia, ya que es efectiva, práctica, y tiene muy poca toxicidad. Con los protocolos de quimioterapia de combinación, la mayoría de los perros con linfoma sobreviven más de un año, y aproximadamente el 25-30% sobreviven más de 2 años (con excelente calidad de vida). La sobrevida promedio de los perros con linfoma que no reciben tratamiento es de aproximadamente 30 días.

El tratamiento de perros con linfoma habitualmente consiste de 4 fases diferentes: **inducción de remisión, mantenimiento, intensificación**, y **re-inducción de remisión**. Durante la **inducción de remisión**, el paciente recibe una combinación de 3 ó 4 drogas, de las cuales una ó más son inyectables; la duración de esta fase varía entre 8 y 12 semanas. Si al final de esta fase, el paciente no está todavía en remisión completa, utilizamos una breve fase de **intensificación**, en la cual administramos una ó dos drogas adicionales con la intención de consolidar la remisión. Una vez que el paciente está en remisión, utilizamos la fase de **mantenimiento**, en la cual administramos dosis bajas de quimioterapia (habitualmente por vía oral), durante un período prolongado. Cuando el tumor sale de remisión, el paciente es tratado con un protocolo de **re-induccion de remisión.**

Otro enfoque terapéutico es utilizar un protocol de quimioterapia más agresivo, sin terapia de mantenimiento. Habitualmente se usan protocolos tipo CHOP (con doxorubicina), durante 3 a 5 meses; el protocolo de la Universidad de Wisconsin es uno de los que se usa más comunmente.

Los protocolos que utilizamos en el Ohio State University Veterinary Teaching Hospital estan en la tabla siguiente.

1) **Inducción de remisión:**
- **Protocolo COAP**:
  - ciclofosfamida (Endoxan) 50 mg/m^2, PO, día por medio en perros, o 200-300 mg/m^2 cada 3 semanas en gatos
  - vincristina (Oncovin) 0.5 mg/m^2 SA, IV, q/1 semana
  - arabinosido de cytosina (Cytosar-U) 100 mg/m^2/day, goteo IV or SQ, durante los 2 primeros días en gatos y los 4 primeros días en perros
  - prednisona 50 mg/m^2, PO, SID durante la primera semana; después 20 mg/m^2 PO, día por medio

ESTE PROTOCOLO SE UTILIZA DURANTE LAS PRIMERAS 8 SEMANAS. DESPUES SE UTILIZA UNO DE LOS PROTOCOLOS DE MANTENIMIENTO.

2) **Intensificación**:
- l-asparaginasa (Elspar) 10,000-20,000 IU/m^2, SQ (una sóla dosis)

3) **Mantenimiento**:
- **Protocolo LMP**:
  - clorambucilo (Leukeran) 20 mg/m^2, PO, cada 2 semanas
  - metotrexato 2.5 mg/m^2, PO, 2 ó 3 veces por semana*
  - prednisona 20 mg/m^2, PO, día por medio
- **Protocolo COAP**:
  - usar como descripto más arriba, pero cada 2 semanas durante 4 ciclos, después cada 3 semanas, y así sucesivamente.

4) **Re-inducción de remisión**:
- **Protocolo D-MAC:** (repetir continuamente durante 12-16 semanas)
  - dexametasona 1 mg/kg, PO ó SQ en los días 1 y 8
  - actinomicina D 0.75 mg/m^2, IV en el día 1
  - arabinosido de cytosina 200-300 mg/m^2, goteo IV durante 4 horas, en el día 1
  - melfalan (Alkeran) 20 mg/m^2, PO, en el día 8 ***(después de 3-4 dosis, usar clorambucilo a la misma dosis en vez de melfalan)***

*The author currently uses the higher dose every other week, since it is not associated with significant toxicity and appears to maintain longer remissions.

Tabla 1. Protocolo de la Universidad de Wisconsin UW 19 (sin mantenimiento)

semana 1:	incristina 0.5–0.75 mg/m^2, IV asparaginasa 400 IU/kg IM o SQ prednisona 2 mg/kg PO q24h
semana 2:	iclofosfamida 200–250 mg/m^2, IV o PO prednisona 1.5 mg/kg PO q24h
semana 3:	incristina 0.5–0.75 mg/m^2, IV prednisona 1 mg/kg PO q24h
semana 4:	doxorubicina 30 mg/m^2 (o 1 mg/kg si <10 kg) IV prednisona 0.5 mg/kg PO q24h
semana 5:	NADA
semana 6:	vincristina 0.5–0.75 mg/m^2, IV
semana 7:	ciclofosfamida 200–250 mg/m^2, IV o PO
semana 8:	vincristine0.5–0.75 mg/m^2, IV
semana 9:	doxorubicina 30 mg/m^2 (o 1 mg/kg si <10 kg) IV
semana 10:	NADA
semana 11:	vincristina 0.5–0.75 mg/m^2, IV
semana 12:	ciclofosfamida 200–250 mg/m^2, IV o PO
semana 13:	vincristine 0.5–0.75 mg/m^2, IV
semana 14:	doxorubicina 30 mg/m^2 (o 1 mg/kg si <10 kg) IV
semana 15:	NADA
semana 16:	vincristina 0.5–0.75 mg/m^2, IV
semana 17:	ciclofosfamida 200–250 mg/m^2, IV o PO
semana 18:	vincristina 0.5–0.75 mg/m^2, IV
semana 19:	doxorubicina 30 mg/m^2 (o 1 mg/kg si <10 kg) IV

DIABETIC KETOACIDOSIS IN DOGS

Donna S. Dimski, DVM, MS, Diplomate ACVIM
Oregon Veterinary Referral Associates
Springfield, OR

'Tis not amiss, ere ye're giv'n o'er, To try one desp'rate med'cine more, For where your case can be no worse, The desp'rat'st is the wisest course.
—Samuel Butler, Epistle of Hudibras to Sidrophel, 1664

Diabetes mellitus is a relatively common disease in dogs. When well regulated, owners have little problem managing the condition. However, in a patient that has not previously been diagnosed, or in a dog that has developed complications such as pancreatitis, diabetic ketoacidosis can result. This metabolic nightmare creates a multitude of fluid, electrolyte, and acid–base irregularities that can quickly turn fatal if not properly managed. In this article, these issues are addressed, problem by problem, followed by a discussion of how they might be corrected.

CLINICAL PRESENTATON OF DIABETIC KETOACIDOSIS (DKA)

The dog with DKA is usually very, very sick. Most dogs present with a history of vomiting, lethargy, and anorexia for a variable period of time (1–5 days). On physical exam, the dog is often clinically dehydrated and depressed. Ketones, smelling like acetone (nail polish remover), can often be detected on the dog's breath. For many people with a "nose" for smelling ketotic breath odor, this is almost pathognomonic for DKA. Other findings could include abdominal pain or icterus (if the dog has concurrent pancreatitis).

The initial workup for a patient suspected of having DKA includes a complete blood count, serum chemistry panel (including lipase), and urinalysis. A urine culture is also helpful. Blood gas analysis can assist in determining optimal fluid therapy choices.

The care of a patient with DKA requires intensive, 24-hour monitoring and in-house laboratory availability for electrolytes, glucose, and blood gases. In many cases, a referral center or emergency/critical care clinic is the optimal choice for a patient with DKA.

The individual metabolic disturbances seen in DKA are addressed in the following sections. We will cover how to correct the imbalance individually, and then summarize the care and monitoring of dogs with DKA.

FLUID DEFICITS

Dehydration is a common problem in patients with DKA. Hyperglycemia causes an osmotic diuresis, and most dogs are unable to keep up with losses by drinking. Additionally, vomiting is very common, worsening fluid losses.

Aggressive fluid therapy should be instituted quickly. Crystalloid fluids are used to treat dogs with DKA. Either 0.9% NaCl or lactated Ringer's solution can be used, and the choice can be based on the initial electrolyte values. If severe hyponatremia is noted, then sodium chloride is a preferred fluid choice. It is often given at a rate designed to recover any dehydration deficit over 10 to 24 hours, in addition to meeting maintenance fluid needs.

METABOLIC ACIDOSIS

In the absence of insulin, glucose transport into cells cannot occur, and the body is in a state of starvation. To cope with this condition, fatty acids are mobilized from adipocytes and transported to the liver. In the liver, the fatty acids are oxidized in the mitochondria into ketone bodies, which can be used by most cells as an alternative energy source. However, the ketone bodies are acidic, and therefore contribute to a high anion gap acidosis. Vomiting, common in most patients with DKA, can also contribute to the metabolic acidosis.

The metabolic acidosis can be quite severe, and patients with blood pH values around 7.0 are not uncommon. Blood gases are the ideal way to identify a metabolic acidosis, but evaluating the bicarbonate concentration on a chemistry panel can also help.

There are several ways to treat metabolic acidosis in the patient with DKA. Some clinicians use sodium bicarbonate routinely, but I prefer to correct the underlying reason for the acidosis by treating with insulin. By providing insulin, glucose is able to enter cells, and production of ketones stops. This quickly leads to resolution of the acidosis. Additionally, treating the patient with an alkalinizing fluid such as lactated Ringer's solution in volumes sufficient to treat dehydration will help resolve metabolic acidosis.

INSULIN DEFICIENCY

Providing insulin is important for many reasons. It stops production of ketone bodies, thus resolving acidosis. It provides the means for energy delivery to the brain, which requires glucose as its only energy source. It also allows for the reduction of severe hyperglycemia, which can result in a severe hyperosmolar condition.

In the ketoacidotic patient, the insulin preparation required is regular insulin, since it has a short duration of action and therefore can be tightly controlled in the sick patient. It can be given intermittently or as an IV infusion. My preference is to give insulin as an IV insulin infusion (Table 1). When giving an insulin infusion, it is important to discard the first 50 mL, since insulin adheres to plastic. The infusion is given and the blood glucose is periodically monitored. When the blood glucose drops to a safer level, then glucose is added to the intravenous fluids and the insulin infusion rate is slowed as needed.

POTASSIUM IMBALANCE

In the patient with DKA, laboratory values for potassium may be high, low, or normal. However, it can safely be assumed that almost all patients with DKA suffer from a whole-body depletion in potassium. Because of the acidosis, intracellular potassium is "traded" for extracellular hydrogen, raising the extracellular potassium, which often is excreted. When insulin is given (correcting the acidosis),

Table 1. Intravenous Insulin Infusion

1. Add 2.2 units/kg body weight of insulin to 250 mL 0.9% sodium chloride intravenous fluids.
2. Connect all needed IV fluid lines which will be used to deliver the infusion to the patient.
3. Open the infusion and discard 50 mL of the infusion, allowing insulin to saturate the tubing.
4. Connect to the patient, and infuse the insulin solution at 10 mL/hour via an infusion pump.
5. Monitor blood glucose initially every 1–2 hours.
6. When blood glucose falls below 250 mg/dL (13.88 mmol/L), decrease insulin infusion rate by 25–50% and provide IV fluids containing 2.5–5% glucose.
7. If blood glucose falls below 100, then the insulin infusion is temporarily stopped.

hydrogen and potassium ions switch back, and potassium is driven intracellularly. This inevitably results in a drop in potassium concentration.

Therefore, potassium supplementation of fluids should be performed even if there is not laboratory evidence of hypokalemia at initial presentation. The amount of potassium supplementation is commensurate with the initial potassium value, but should never exceed 0.5 mEq/kg/hr.

PHOSPHORUS AND MAGNESIUM IMBALANCE

Once insulin therapy has commenced, decreased concentrations in phosphorus and magnesium may become problematic. When insulin is available and glucose enters cells, phosphorus goes intracellularly as well, and this may create an extracellular deficit of phosphorus. Clinical effects of hypophosphatemia include hemolytic anemia and neuromuscular signs such as weakness. If serum phosphorus concentrations drop below 2.0 mg/dL (0.65 mmol/L), then phosphorus supplementation should be instituted using potassium phosphate. The amount of potassium provided by this preparation needs to be subtracted from any needed potassium supplementation being provided.

Magnesium deficiency may be difficult to diagnose in dogs with DKA. It may occur secondary to decreased oral intake and increased renal loss. Severe magnesium deficiency may result in neuromuscular weakness and cardiac arrhythmias. If needed, magnesium can be supplemented in an IV solution of magnesium chloride.

DKA: ADMISSION TO DISCHARGE

Let's imagine an 8-year-old, female spayed mixed breed dog named "Example" with a 6-week history of polyuria/polydipsia and weight loss. In the past week she has been progressively more lethargic and inappetent, with 48 hours of severe illness and vomiting.

On exam, Example weighs 10 kg, has a temperature of 98.5°F, pulse rate of 140 bpm, and respiratory rate of 24 per minute. She is very depressed and about 10% dehydrated. She has an obvious ketone odor to her breath. Heart and lungs sound normal, and abdominal palpation is normal. No other abnormalities are detected on physical exam.

We obtain blood for an in-house CBC, chemistry panel, electrolytes, and blood gases. We obtain urine for a urinalysis and urine culture. While we await those results (about 20 minutes), our technicians place a double-lumen jugular catheter. This catheter allows us to administer glucose-containing fluids in one line, and administer other fluids (such as an insulin infusion) and periodically sample blood through the other line.

The CBC shows a mild mature neutrophilia. The chemistry panel shows elevations in liver enzymes, and a blood glucose of 522 mg/dL (28.98 mmol/L). Sodium and potassium values were both in the normal range. Bicarbonate was low at 12 IU/L (12 U/L). Blood gases confirmed a metabolic acidosis.

We calculated Example's fluid deficit at 1000 mL, which we chose to correct over 12 hours at 83 mL/hr. Her fluid losses from vomiting were estimated at 10 mL/hr. Her maintenance fluid needs were 27 mL/hr. Therefore, her initial fluid rate was 120 mL/hr. We chose to use lactated Ringer's solution, and supplement it with 30 mEq KCl/L, since the initial potassium concentration was normal, but we assumed her total body potassium was low. At a rate of 120 mL/hr, the potassium was being infused at (0.3 x 120) = 3.6 mEq/hour, which is safely below the limit of 0.5 mEq/kg body weight per hour (in Example's case, this would be 5.0 mEq/hour).

We then set up her insulin infusion. We added 2.2 units/kg of regular insulin (in Example's case, 22 units) to a 250 mL bag of 0.9% saline, hooked up an infusion set, and discarded the first 50 mL. We initiated the insulin infusion in the other jugular line at 10 mL/hr, decreasing the other line's fluid rate by 10 mL/hr.

After two hours, we rechecked her blood glucose. It had dropped to 343 mg/dL (19.04 mmol/L), and her body temperature was 100.1°F. After 4 hours, her blood glucose was 219 mg/dL (12.07 mmol/L), sodium and chloride were normal, and potassium had dropped to 2.9 mEq/L (2.9 mmol/L). Her fluid was switched to 0.45% NaCl with 2.5% dextrose supplemented with 40 mEq KCl/L, and her insulin infusion was decreased to 7.5 mL/hour. Over the next 12 hours, her blood glucose was checked every 2 hours, and her insulin infusion was changed up or down by 25% to keep her blood glucose between 150 and 300. After 12 hours, her fluid rate was changed back to maintenance fluids, since her dehydration seemed to be resolved.

Twenty-four hours after admission, Example seemed brighter and more alert. She last vomited 12 hours before. She no longer had ketotic breath odor and was normothermic with a normal heart rate. Her electrolytes were normal, and her blood glucose was 241 mg/dL (13.38 mmol/L). She was offered small amounts of water every hour, which she drank eagerly without vomiting. Later that day, she was offered a small amount of a bland canned dog food, which she ate. She continued on the fluids and insulin infusion overnight, with glucose checks reduced to every 4 hours.

Forty-eight hours after admission, Example was very bright and alert. She was offered food and ate eagerly, so she was given 6 units of NPH insulin subcutaneously, and the IV insulin infusion was stopped. Water was offered at all times. Blood glucose 6 hours after insulin was 151 mg/dL (8.38 mmol/L), and 12 hours after insulin it was 278 mg/dL (15.43 mmol/L). An evening dose of 7 units NPH insulin was given subcutaneously, and she was fed.

Seventy-two hours after admission, Example was very clear that she wanted to go home. Her morning glucose was 244 mg/dL (13.54 mmol/L), and she was eating and drinking well. Her jugular catheter was removed, and she was given 7 units of NPH insulin subcutaneously. She was discharged to her owners with instructions on insulin administration, and the plan was for the owners to administer 7 units of NPH insulin twice a day, with changes as needed.

Example did very well. She recovered quickly, and had few complications. She did not have any problems with phosphorus or magnesium, and did not have other diseases that make treatment more difficult, such as pancreatitis or a severe infection such as pneumonia or pyelonephritis. But, that's why she's an Example! In real life, things seldom go quite that easily. What is true about treating the patient with DKA is that anticipation of complications is the best treatment. If you anticipate problems such as hypokalemia and acidosis, then early treatment will often result in lifesaving results.

CANINE HYPOTHYROIDISM: MYTH VERSUS REALITY

Thomas K. Graves, DVM, PhD, Diplomate ACVIM
College of Veterinary Medicine
University of Illinois, Urbana, IL

Authors almost always refer to hypothyroidism as a common (if not the most common) endocrine disease in dogs, and, while it may be true, there is little evidence to support this claim. In fact, canine hypothyroidism may be one of the most over-diagnosed diseases in small animal medicine. Just about any medical disorder can be associated with decreases in circulating concentrations of thyroid hormone, causing hypothyroidism to be over-diagnosed. In addition, it is common practice for veterinarians to treat hypothyroidism empirically following a presumptive diagnosis. This practice is not recommended for several reasons. First of all, it is not scientifically sound medical practice. Second, it may allow another disorder to progress undiagnosed. Third, unnecessary supplementation with thyroid hormone disrupts the normal regulation of thyrotropin-releasing hormone (TRH), thyroid-stimulating hormone (TSH), and thyroid hormone production, the consequences of which are not understood.

Clinical signs of hypothyroidism result from generalized decreases in metabolic functions supported by thyroid hormone action. The clinical signs of hypothyroidism are multisystemic and varied. Their onset is gradual. The classic presentation of a hypothyroid dog includes obesity, inactivity, mental dullness, decreased appetite, dermatologic abnormalities, and intolerance to exercise and cold. These signs may or may not be present in all dogs with hypothyroidism.

Dermatologic abnormalities are the most common presenting complaints of owners of dogs with hypothyroidism. Approximately 85% of hypothyroid dogs are reported to have skin lesions. Care should be taken in interpreting the reports of the prevalence of dermatologic signs in canine hypothyroidism because many of the reports have been written by dermatologists. Whatever the true incidence of these signs, they include alopecia (arrest of hair growth cycle in the telogen phase), dryness, scaling, dull hair which is easily epilated, seborrhea, slow hair re-growth, various degrees of hyperpigmentation, poor wound healing. In extreme cases, mucopolysaccharides accumulate in the skin causing it to thicken, especially in the face. This condition is called *myxedema*. Dogs with myxedema are classically referred to as having “tragic” facial expressions. The typical skin problem of canine hypothyroidism is usually not pruritic, although secondary bacterial infections are possibly, and could cause a degree of pruritis. Hypothyroidism is also commonly mentioned as an underlying cause of chronic ear infection. There is little or no scientific support for this claim.

MYTH OR REALITY: HYPOTHYROIDISM IS A CAUSE OF OTITIS

Hypothyroidism is commonly cited as a cause of bacterial pyoderma, which can occur locally, manifesting as otitis externa (infection of the outer ear). In a recent paper the author stated, “Recurrent bacterial and yeast infections of the skin and ears often occur secondary to hypothyroidism and may be the only presenting signs,” although the statement is not supported by any reference to a published study. It is commonly stated in articles and textbooks that hypothyroidism can cause decreased function of lymphoid cells, decreased T-cell function, decreased humoral immunity, and decreased barrier function of the skin. Evaluation of these statements and associated references shows a considerable lack of supportive evidence. Authors' personal observations are commonly cited, as is one research paper in mice published in 1980. Examination of that reference reveals that it is not a study of hypothyroidism at all, but rather a study of the effects of thyroid hormone excess on the immunologic response to administration of sheep red blood cells in mice. The effects were minimal. While there are some studies (not in dogs) showing that thyroid hormone has some effects on the immune system, athyreotic human patients have been shown to have similar white blood cell function when compared with normal controls. There is no published evidence to suggest that otitis externa, especially as the sole clinical sign, is a feature of hypothyroidism in dogs.

MYTH OR REALITY: HYPOTHYROIDISM IS A CAUSE OF NEUROLOGIC DISEASE

Many neurological signs have been blamed on hypothyroidism in dogs. Bicshel et al reported 4 dogs with neurological diseases associated with low concentrations of serum total T4 and inadequate responses to exogenous TSH administration. Three of the dogs had no non-neurological clinical signs of hypothyroidism. One was a 7-year-old boxer with facial paralysis that was also treated with sulfamethoxazole, a drug known to cause severe hypothyroidism. Another was an 11-year-old Old English sheepdog with a head tilt that did not resolve on thyroxine therapy. Another was a 10-year-old cocker spaniel with circling and a head tilt that did not respond to thyroxine therapy, and the other was a 10-year-old mixed breed dog with vestibular signs (head tilt, abnormal eye movements, loss of balance) that resolved. Idiopathic vestibular disease, which is clinically similar, is common in older dogs, and resolves spontaneously as well. In another paper by Jaggy et al, 29 dogs with hypothyroidism (diagnosed by TSH stimulation testing) and neurologic signs were studied retrospectively. Eight of nine dogs with vestibular disease recovered on thyroxine replacement therapy. Four dogs with megaesophagus did not recover despite thyroxine therapy. Of the 29 dogs studied, only 10 had increased concentrations of serum cholesterol. This common biochemical finding is usually present in more than 75% of dogs with hypothyroidism, leaving room for doubt that many of the dogs in the study actually had hypothyroidism.

But what about the TSH stimulation test results in the dogs with reported hypothyroidism and neurological disease? The TSH stimulation test is not perfect, and even though it is considered a gold standard test for hypothyroidism, it can be difficult to interpret. Even its position as a gold standard is in question. A recent study of dogs with low T4 and thyroid biopsy results showed that the TSH stimulation test is often false positive. This report also supported earlier reports showing the overlap between total T4, free T4, and endogenous TSH concentrations in sick versus hypothyroid dogs.

MYTH OR REALITY: HYPOTHYROIDISM IS A CAUSE OF INFERTILITY

Hypothyroidism has been implicated as a cause of infertility in both male and female dogs. It should be noted that the most common reason for infertility in dogs is mistiming of breeding. Still, bitches failing to conceive are often treated empirically with thyroid hormone supplementation. Early investigators reported sperm abnormalities in dogs with hypothyroidism. More recent studies have shown no effect of experimentally induced hypothyroidism on testicular size, sperm count, motility, or morphology, although actual fertility studies have not been done.

MYTH OR REALITY: HYPOTHYROIDISM IS A CAUSE OF AGRESSION

Recently, hypothyroidism has been implicated as a cause of aggression in dogs. Only a handful of cases appear in the literature. In all cases, physical examination findings and results of CBC and biochemistry profiles were normal. All dogs had low serum T4 and high TSH concentrations. All but one were intact males. One dog responded to thyroid supplementation, but was also castrated and subjected to behavioral modification therapy. The other dogs did not respond to treatment.

MYTH OR REALITY: VACCINES CAUSE HYPOTHYROIDISM

Hypothyroidism is an immune-mediated disease, and attempts have been made to blame the presence of canine immune-mediated diseases on over-vaccination. In one study, dogs were vaccinated repeatedly at 8, 10, 12, 16, 20, 26, and 52 weeks of age and antibodies against thyroglobulin were studied. Thyroglobulin is a key protein involved in thyroid hormone production, and antibodies against this protein are routinely measured as a test for the presence of an immune-mediated thyroiditis. In the study, antibodies were higher in excessively vaccinated dogs than in control dogs. In a subsequent study by the same authors, however, the thyroid glands of over-vaccinated dogs were not different from unvaccinated dogs. If anti-thyroglobulin antibodies truly do indicate the presence of lymphocytic thyroiditis (the most commonly cited type of immune-mediated thyroid disease causing hypothyroidism), there should have been more inflammation found in the over-vaccinated dogs. There are lots of possibilities for why antibody tests could be positive when there is no underlying immune-mediated thyroid disease, but it cannot be explained in the context of hypothyroidism.

HOW IS HYPOTHYROIDISM DIAGNOSED?

The measurement of both total T3 and total T4 are commonly performed in canine practice. There is diagnostic value to the determination of TT4, because a finding of a normal TT4 excludes a diagnosis of hypothyroidism. The finding of a low basal TT4, however, is of little diagnostic value, because TT4 concentrations are falsely lowered by just about any concurrent illness, and by a large number of drugs, including benzodiazepines, phenobarbital, glucocorticoids, imidazoles, penicillins, sulfonylureas, salicylates, and phenothiazines. Unfortunately, many dogs are diagnosed with hypothyroidism based only on findings of low TT4 concentrations. Measurement of serum TT3 is without value in the diagnosis of thyroid disorders in dogs.

Most thyroid hormone circulates bound to plasma protein. Approximately 1% of TT4 is not protein-bound and is referred to as free T4. In true hypothyroidism, basal free T4 concentrations should be low, and most of these measurements in hypothyroid dogs are low. There is, however, a degree of overlap with normal dogs and dogs with non-thyroidal illness, so this test alone does not confirm a diagnosis of hypothyroidism.

The combination of free T4 and serum TSH measurement is considered nearly 100 percent diagnostic for hypothyroidism in people. Unfortunately, the results of serum TSH measurement are not nearly as clear-cut in canine hypothyroidism. Most dogs with primary hypothyroidism, as expected, have high concentrations of TSH in the serum. Serum TSH concentrations, however, are normal in some dogs with hypothyroidism, making this test less reliably in this species.

Thyroid autoantibodies—antibodies against thyroglubulin, T4 and T3—are considered to be a marker for lymphocytic thyroiditis. Probably the most consistent, although by no means absolute, antibody found in dogs with hypothyroidism is anti-thyroglobulin antibody. This test may be of some use, when combined with other findings, in the diagnosis of hypothyroidism. False positives and false negatives occur.

In the past, the most reliable test for canine hypothyroidism was the TSH stimulation test. Exogenous TSH administered to a normal dog causes a consistent rise in the serum concentration of TT4, whereas dogs with hypothyroidism exhibit little or no response to TSH. While there were plenty of gray areas in interpreting this test, it was considered a very useful diagnostic tool. Recent work has called the validity of the test into question and has suggested that quantitative scintigraphy may be the most accurate test.

Therapeutic trials are often recommended for diagnosis of hypothyroidism in dogs, but caution is warranted in the interpretation of test results. Regrowth of hair, for example, following thyroid hormone supplementation does not necessarily implicate thyroid hormone deficiency as a cause of alopecia. Studies have shown that thyroid hormone accelerates hair growth and wound healing in euthyroid mice and rats. It's possible, if not probable, that thyroid hormone stimulates these processes in euthyroid dogs as well.

Short of being confirmed by an invasive diagnostic procedure such as a thyroid biopsy, a diagnosis of hypothyroidism in a dog should depend on the finding of appropriate clinical signs, a low free T4, and some of the following results: high TSH, positive anti-thyroglobulin antibodies, hypercholesterolemia. Less stringent criteria may result in the overdiagnosis of the disease.
